It seems that if a general stimulation occurs as denoted by an increased rate, weight, and tone, symptoms are less likely to occur; that the lower the rate without increase, the more possible for symptoms to occur; and, finally, that sudden dropping of the rate is associated with development of symptoms. These changes are not necessarily due to thyroid gland activity or

Plate V

Plate VI

to be three months pregnant. There were two patients with missed abortions, one with rate of plus 26, and the other minus 10. One patient with hydatidiform mole was metabolized when first seen in the fourth month of pregnancy. She was in a severe degree of dehydration and acidosis. Vomiting had begun at six weeks, was continuous, and was gradually increasing. The loss of weight was 20 lb. and the blood pressure was 90/70. Aschheim-Zondek test was positive with 1/150 c.c. of urine. This patient had not been metabolized be-

fore pregnancy, but when metabolized one year later was minus 12.

During the second trimester, which is perhaps the uneventful period of pregnancy, 155 cases were studied. Twenty-five cases showed a decrease in rate, while 18 had practically no change. The remaining showed a gradual increase, and with this progression had a general improvement in their physical and mental condition. In those 25 cases of decreased metabolism, and likewise in those 18 cases of stationary metabolism these improvements were slower to develop. During this trimester some patients showed a tendency toward unstable metabolism. This was indicated by the patient suddenly becoming extremely nauseated, followed by violent vomiting. Several cases had to be taken to the hospital and treated for acidosis. In all these patients there seemed to be an associated drop in the metabolic rate prior to the

In the plus group, the greatest weight increase took place in the last trimester, although an average of babies' weight for this group was 7 lb. 4 oz. In the minus group, the greatest increase occurred in the middle trimester, and the average babies weight was 7 lb. 9 oz. In these cases the mothers did not seem to gain as much weight on their bodies. (Plate V.)

The third trimester, the constructive period, the time of greatest fetal growth was studied. In most women pregnancy during these months has a stimulating effect. Intestinal absorption is certainly increased, weight is gained, the woman has a feeling of warmth, she has more ambition, and the blood pressure is increased slightly. During this time the toxemias are apt to occur and labor may begin prematurely. It was thought interesting to see if there was a greater tendency for these complications to occur in the minus group or in the plus group. There were 3 cases of toxemia in the plus group, one pre-eclampsia and 2 cases of chronic nephritis. In the minus group there were 5 cases of toxemia, one nephrosis, 3 pre-eclampsia, and one post-partum eclampsia.

Unusual condition of babies was noted as follows: In the plus group there was one malformed premature hydrocephalic child, and in the minus group 3 malformed children were born. All were premature and died. One mother whose metabolic rate steadily decreased through pregnancy delivered a Mongolian idiot with squinty eyes and thick tongue. This child improved on thyroid extract, but since has developed into a definite Mongolian idiot.

It seemed that in the plus group labor was tolerated better, there was less tendency for acidosis to develop during labor, and the general improvement afterward seemed faster. The average length of labor in the plus group was 9.2 hours, while in the minus group it was 12.5 hours.

The thyroid seemed to have the most increase in size in the plus group, and there was a tendency for slightly higher blood pressure readings. Although thyroid plays an important part in pregnancy and may be responsible for many conditions, it is not felt that the metabolic rate is an indication of thyroid function alone.

Included in this series are 2 patients who developed hyperthyroidism during pregnancy, 4 women that had had the thyroid removed prior to pregnancy, and 3 patients with twins.

Plate VII

period of acidosis, and all were definitely the type of individuals having low rates. This condition is very apt to occur just before or during the time of the month that a menstrual period would ordinarily be due.

During the prenatium, weight changes were interesting. It was noted that the average gain for all cases was 22 lb. The group below minus 10 at the beginning of pregnancy showed an average loss of 2 lb. in the first trimester, a gain of 11 lb. in the second trimester, and an increase of 3 lb. in the third trimester, making an average of 16 lb. increase throughout. In the plus rate group, there was an actual increase in the first trimester, a gain of 11 lb. in the second trimester, and an increase of 11 lb. in the third trimester.

Weight increase in the mother in respect to the time of fetal growth is of interest.

It has been thought that the fetal tissue causes the increase in metabolism in pregnancy. Three cases of twins were studied and present the following curve: In all cases the abdominal distention was severe. The curve, however, seems to appear almost the same as the normal, with the exception perhaps of slightly more increase during the latter part of the second trimester and during the third trimester. (Plate VI.)

Women who have had their thyroids removed have always given the obstetrician considerable concern during subsequent pregnancies. Four patients with thyroidectomies were studied.

CASE 1.—The first patient had had her thyroid removed in stages at the age of 23. Shortly afterward she became pregnant. The pregnancy was normal. The patient had always retained some exophthalmos, mild nervousness, and tremor. Her basal metabolism was plus 14 just prior to her second pregnancy. When one month pregnant, the metabolism increased to plus 26 and remained high. (Graph I, Plate VII.) Blood pressure was 160/80. She felt well except for nervousness and loss of appetite. When she was three months pregnant she began to flow; and one month later had a missed abortion.

CASE 2.—Mrs. H. R., age 33, married ten years, first pregnancy eight and a half years ago. It was normal and without symptoms. Two years later, the patient developed severe hyperthyroidism. The thyroid was removed and was of the very active type. The patient then tried for several years to become pregnant. Her basal metabolism was minus 17. Graph II, Plate VII. Finally she conceived, and upon missing her first period extreme nausea began and she vomited continuously. Hospitalization was necessary and after intravenous glucose she improved enough to be allowed to return home, but symptoms continued until the sixth month. Thyroid was given from the fifth month on. She lost 7 lb. of weight in the first trimester, and there was a drop in blood pressure of 40 points. Blood sugar was 76 mg. Delivery and baby were normal. Plate VIII shows section of thyroid removed. Small follicles are present with columnar type of cell and vacuolization of colloid.

CASE 3.—Mrs. J. R., age 30. Thyroidectomy seven years ago. The first pregnancy two years later was uneventful except for nausea and vomiting throughout. Since the first pregnancy she had had irregular periods. Basal metabolism was minus 1. The second pregnancy occurred last spring. (Graph III, Plate VII.) As soon as the first period was missed, nausea and vomiting began. Metabolism was zero. When three months pregnant, she became violently ill, headache so severe that sedatives could not control it, vomiting continuous, and patient was hospitalized. Temperature was 102°F., pulse 120, blood pressure 90/70, urine acetone 4 plus, and blood sugar 77 mg. Metabolism had fallen just prior to this to minus 15. She was treated for acidosis and within a few days was able to go home. Metabolism, blood pressure and weight increased, and delivery and baby were normal. Weight of baby

was 7 lb. 5 oz. Plate IX shows section of removed thyroid. Follicles are somewhat larger than would be expected. There is considerable vacuolization.

CASE 4.—Mrs. S., age 37. First pregnancy ended in miscarriage; second was twins, one baby dying; third pregnancy was uneventful except for diarrhea and indigestion. Eight months after the third pregnancy, patient had a very toxic thyroid removed. (Graph IV, Plate VII.) Metabolism was plus 55. Four months later, she became pregnant for the fourth time, and was normal except for rather severe nausea and vomiting the first three months. She developed a real hypothyroid condition as indicated by symptoms and drop in metabolism to minus 22. Plate X shows section of removed thyroid. This thyroid was very active, showing a germinal center of lymphocytes. There was marked vacuolization of the small follicles with high columnar epithelium.

Plate VIII

Patients developing thyroid disease during pregnancy, or pregnant women with hyperthyroidism are rather rare. Two were seen during pregnancy, but unfortunately only one was metabolized as often as desired. The other was first seen when she was seven months pregnant. She was extremely toxic, having an associated pre-eclamptic toxemia. Metabolism at that time was plus 45. The heart was fibrillating, and blood pressure was 200 to 220. Labor began at seven and a half months, and a two-pound, ten-ounce baby was delivered. Six weeks after delivery, the metabolism had decreased to plus 18. Three months later, she again became toxic

with the usual signs of hyperthyroidism. Metabolism was plus 45, and the thyroid was removed. Microscopically it is shown in Plate XI. Section of adenoma of thyroid—adenomatous on left and thyroid tissue on right with mild activity.

The second patient had had an enlarged neck since childhood. During pregnancy it increased in size, and the metabolism increased to plus 17. She felt well and was not nauseated, but there were mild signs of hyperthyroidism such as tremor, pulse 100 to 120, and blood pressure 130/80. Three months after delivery the thyroid was removed, and pathologically showed (Plate XII) moderately active thyroid tissue, but not as active as would

was attempted. This showed a small increase at the sixth week, followed by a lowering in the second, third, and fourth months. Then there occurred a gradual increase to a plus quantity.

(2) Fifty-six per cent of all patients were within normal limits in the first trimester, 71 per cent in the second trimester, and 75 per cent in the last trimester.

(3) The optimum basal rate is one that begins between plus 10 and minus 10, and has a slow gradual increase.

(4) The less desirable cases are those that start below minus 10 and have a gradual increase.

Plate IX

Plate X

be expected from signs and symptoms during pregnancy. Four months after removal, metabolism was minus 22.

The first case showed marked increase in thyroid in the last trimester. The second case also showed increased size of gland in the last three months, but not of as severe degree as the first case. Size of the first baby was 2 lb., 10 oz.; the second baby was 6 lb., 8 oz. Neither case had nausea or vomiting in the early months.

CONCLUSIONS

(1) After a study of 1,250 basal metabolisms, a normal rate during pregnancy

(5) The least favorable cases are the ones that are below minus 10 and continue to go lower, and those who have a drop of 15 points or more, no matter at what level they begin.

(6) Symptoms develop in a larger percentage of patients in the latter type of curve.

(7) In 13 cases of miscarriage, 10 patients, or 76 per cent, had a metabolic rate below zero. Four patients were below minus 10. This, however, does not mean much because 77 per cent of the normal patients presented levels as low.

(8) One patient with hydatidiform mole had a metabolism of minus 27, with severe nausea, vomiting, and acidosis.

(9) The second trimester presents fewer abnormal conditions, but patients failing to increase their metabolism are more prone to vomiting and acidosis.

(10) Maternal weight increase was greater in the plus group than in the minus group.

(11) Weight of babies was greater in the minus group than in the plus

(12) Average length of labor was longer in the minus group by three hours, and labor was not tolerated as well in the minus group.

haps, that during the last trimester thyroid activity is increased. This would lead us to watch carefully a patient developing hyperthyroidism in the first three months, at which time the thyroid function is at its lowest, because of the possibility of the third trimester causing too excessive activity.

713 E. GENESSEE STREET

DISCUSSION

DR. J. THORNTON WALLACE. My interest in Doctor Hughes' subject began some years ago in the study of the relation of thyro toxicosis to pregnancy. Certainly not in our hospital and clinic, nor in the literature have I found any series of cases comparable either in number or

Plate XI

Plate XII

(13) There were more malformed babies in the minus group.

(14) Three cases of twins presented metabolic curves similar to normal, except for slightly higher values in the second and third trimesters.

(15) Four cases of thyroidectomies were followed during pregnancy. One was normal except for moderate nausea and vomiting. Two cases of hyperactive thyroids were followed. Both had increased activity in the last three months. Both thyroids after removal were not as active as would be expected, showing per-

in detail of study to that reported to-day. Such scattered reports as have been made are of from one to eighty-five cases, and in many instances have come from physiologists and biochemists. Such a study as this, conducted by a clinician actively engaged in the practice of obstetrics, is not only timely but of the greatest value in its application to the practical problems involving this subject that confront the obstetrician. Its value is further enhanced by the fact that the studies have been made by one man who has known first hand all factors concerned in each case and among a group of women representing a good cross section of American life. So thoroughly and completely has the subject been covered by Doctor Hughes that I can do no better than to pick out from his paper those points which I consider worthy of further

emphasis and call them once again to your attention.

His is the first heretical voice that I have heard raised against the until now generally accepted idea that in the majority of pregnant women the metabolic rate rises in the last trimester from 15 to 25 per cent above the normal for the nonpregnant woman of like age and surface area. When one looks more critically into previous reports in the literature, he finds that the conclusions drawn by Sandiford and Wheeler were from the study of a single case, which while thorough enough in itself, would hardly warrant generalization. In the 47 cases reported by Rowe and his associates, more than half were from a group of young, unmarried mothers, most of whom were under sixteen, and whose immature ages alone might have given rise to more than normal variations. Stander and Peckham in their 13 cases were working with toxemic subjects only, and while they were unable to state definitely that the toxemia influenced the basal rate to any marked degree, it might nevertheless have been responsible for the rise recorded. Zuntz, Hasselbach, Carpenter, and Murlin have all reported a rise of approximately 4 per cent over the nonpregnant state, a figure so small as to be easily within the realm of normal error or variation. The largest series of cases have come from Cornell and Baer. Both report a rise of from 33 to 35 per cent above the normal nonpregnant rate, a figure out of all proportion to most reports. With so wide a variation in figures as 4 to 35 per cent already occurring in the literature, it is to be wondered just what the true figure is, and would seem not only to justify the work done by Doctor Hughes but to call for even more careful investigation along this line.

As to a cause for the rise in rate during the last months of pregnancy reported by most observers, opinion differs. Some would attribute it to a simple increase in protoplasmic mass, others to an increase in thyroid activity, indicated by an easily measured increase in the iodine content of the blood, many to a combination of these two factors, a few to some hormonal influence, while most would frankly admit that the cause is unknown. Thus is illustrated again the chaotic state of our knowledge on this subject. As against the theory of protoplasmic increase raising the basal rate may be cited the 3 cases of twins followed by Doctor Hughes, where while the fetal protoplasmic mass increased abnormally, the basal rate failed to rise proportionately.

I have not found any one in the literature who has tried so extensively as Doctor Hughes to correlate various clinical symptoms with the changes in the metabolic rate. All are thoroughly familiar with the relation of hyperthyroidism as indicated and measured by the elevation of basal metabolic rate to hyperemesis gravidarum and its dramatic amelioration by the administration of Lugol solution, but nowhere have I seen described the relation of a rapid drop in metabolic rate to the vomiting, acidosis, dehydration and prostration of early pregnancy brought out by the work of Doctor Hughes. With such a thought in mind, it is hardly too much to hope that some one may give us a definite therapeutic measure for the prevention of this distressing

state. Again, his comparison of maternal and fetal weight gain with metabolic changes is the first such comparison that has come to my attention.

I think it has been the common feeling of most of us that those women of the so-called sub- or hypothyroid group along with the hypopituitary group are prone to have irregular and abnormal labors, but here Doctor Hughes has given actual figures to show that women with lowered basal rates, possibly or presumably due to lowered thyroid activities, either primary, or secondary to a general endocrine imbalance, are likely to have such. Just as it has been claimed by some that long, nagging labors may be predicted by the finding of a narrowed pituitary bed in an x-ray of the skull, who knows but that such a prediction may sometime be made possible by characteristic changes in the metabolic rate and some therapy designed to offset it.

His observations regarding spontaneous abortions where it was shown that out of 13 cases 10 had a lowered or at least a minus rate, while not conclusive is at least confirmatory evidence in favor of the commonly held opinion that patients with lowered thyroid function are less likely to become pregnant and more likely to abort. Litzenberg and Carey have written extensively and well on this particular phase drawing their conclusions from a series of 2,500 basal metabolisms, mostly in sterility cases. I am sorry that his group of cases did not afford more material of the hyperthyroid type in order that he might have given even more weight than did his two cases to the idea that the hyperthyroid with elevated rate and other characteristic symptoms is even more unlikely to conceive and much more apt to abort, miscarry, or have a premature labor, than the hypothyroid.

His experience with previously thyroidectomized patients has differed somewhat from ours in that in none of that group did we have any abnormal labors, abortions or miscarriages. None suffered more than the usual discomforts of pregnancy. However, in neither of our series have there been enough cases for definite conclusions to be drawn.

The finding of a greater number of fetal anomalies among the minus than the plus group is of particular interest to me. Doctor Hughes has reported in 48 mothers suffering from tyrotoxicosis, 7 babies with meconium neonatorum, 2 congenital cardiac and 4 anencephalics. We had one mother who was known to have suffered from tyrotoxicosis through six pregnancies and whose fifth baby had a congenital heart lesion, and her sixth a hair lip and cleft palate. More data of this kind will be helpful in determining whether fetal anomalies are more common in hypo- or hyperthyroid mothers than they are under normal conditions.

In conclusion, I would like to voice a plea for more work of this kind, and more effort directed toward the study of changes in metabolic rate and its relation to symptoms than has been done in the past. In this way, and in this way only, will a true picture of the metabolic rate for the pregnant woman be established and its value as a clinical guide determined.

PROPHYLACTIC POSTOPERATIVE ROENTGENOTHERAPY FOR CARCINOMA OF THE BREAST

MAURICE LENZ, M.D., VIRGINIA KNEELAND FRANTZ, M.D., and HAIG H. KASABACH, M.D.

*From the Departments of Radiotherapy and Surgical Pathology of the Presbyterian Hospital,
New York City*

Prophylactic roentgenotherapy following mastectomy for carcinoma of the breast has been in use for over twenty years, yet there is disagreement as to its merit¹⁻⁵ and the best method of its application.⁶⁻⁸ Evaluation of this treatment has been based chiefly on gross statistical comparisons of survival periods with and without postoperative roentgenotherapy, while factors bearing on the natural life cycle of the tumor have not been given sufficient consideration. Uniform statistical grouping of divergent clinical histories may be misleading, as illustrated by two following cases from our series: In one, radical mastectomy and postoperative roentgenotherapy were instituted after the tumor had been noted twelve years; the patient remained well for seven years thereafter. In a second, radical mastectomy and postoperative irradiation were started one month after the tumor became apparent, yet the patient died five months following operation. It would be manifestly unjust to credit the long survival in the first case to treatment, or condemn it on the basis of the second experience; the clinical course in both cases was not determined by the treatment as much as by factors inherent in the tumor and host. Other inaccuracies, depending on our methods of diagnosis of cancer, have also not been taken into sufficient account; not only are we unable to appreciate clinically microscopic foci of cancer, but even larger masses, *e.g.*, in the internal mammary chain of lymph nodes, completely escape early recognition; inflammatory thickening⁹ and fat necrosis¹⁰ in the mastectomy field are frequently mistaken for recurrence and chronic adenitis of the supraclavicular region for metastases. The use of great numbers of cases in statistical studies can only partially overcome this shortcoming, and at times a better insight into conditions may be obtained by a detailed study of a smaller series.

Usually, irradiation is limited to the operative field on the chest wall and the adjoining supraclavicular and axillary

regions. It is generally accepted that the majority of carcinomas of the breast are radioresistant, *i.e.*, intensive irradiation is required to affect them. However, the thin, scarred, poorly nourished skin flaps in the axilla and anterior chest wall remaining after a thoroughly done mastectomy cannot support vigorous x-ray dosage. The dosage given in this area is usually kept low and it is not surprising that 8 of 9 cases of skin metastases in our series, started in the irradiated operative area of the anterior chest wall. Logically, postoperative prophylactic x-ray therapy of cancer of the breast should not be limited to the usual areas of local extension, but should also include the commonest sites of metastases, *i.e.*, the lungs, bony pelvis and intervening lymphatics.¹¹ This, however, is impractical, as the body does not tolerate intensive irradiation over extensive areas.

Fear of post-irradiation pulmonary sclerosis has led to attempts, to exclude the lungs from the area of irradiation, by skimming the chest wall with tangentially placed fields.¹² The impracticability of limiting the x-ray beams to the exterior chest and yet administering sufficient dosage to destroy retrosternal metastases seems too evident to need further elucidation. On the contrary, this subpleural part of the lungs must of necessity be over-irradiated in this method. Nevertheless there is a scarcity of reports of authentic cases of pure pulmonary sclerosis even after the much more intensive roentgenotherapy. The majority of suspected instances prove at autopsy to be connective tissue replacements of cancerous metastases.

Discussion of whether to use small doses (300 r) repeated at bimonthly intervals for two years postoperatively,^{7,8} or to administer full erythema doses repeated four to eight times at monthly intervals,⁹ was settled in favor of the former method, at the Congress of the German Roentgen Society, in 1926. Many clinics have since adopted this technic and are using 130 K.V. and 3 mm. Al. Growth restraint of

radiosensitive, incompletely removed carcinomatous infiltrations in the superficial layers of the chest wall, axilla, or supraclavicular region, may occasionally be obtained by this technic. For instance: One of our cases with extensive skin metastases, invading the mastectomy area "en cuirasse," was partially controlled for the succeeding three and a half years by the administration during this period of seven cycles of x-ray treatments, with 125 K.V. and 3 mm. Al., at 10 in. T.S.D. Though similar irradiation did not prevent the postoperative appearance of skin metastases on the irradiated chest wall in 7 other cases already mentioned. Handley's contention that many skin metastases are surface extensions of cancerous spread along the lymphatics of the deep fascia^{13,14} must be borne in mind, as postirradiation invasion of a thoroughly irradiated field, may, perhaps, explain many an irradiation failure. In 2 of our cases the first postoperative appearance of skin nodules was noted near the sternocostal junction of the second rib, *i.e.*, overlying the corresponding, internal mammary lymph nodes, emphasizing the need for efficient radiotherapy, of this surgically inaccessible region.^{13,14} While the internal mammary lymph nodes lie at the edge of, and not behind the sternum, the absorption of irradiation by this bony structure may become important if the sternum is included in the field of irradiation and low or medium voltage x-rays are used. If this absorption is measured by interposing an average 8 mm. manubrium sterni between the x-ray tube operating on kenetron rectification with an unsmoothed current, and an ionization chamber, the following proportion of absorption will be found: 25 per cent if 108 K.V. and 0.25 mm. Cu. plus 1 mm. Al. are used; 17 per cent if the voltage is 130 K.V. and the filter 3 mm. Al.; and only 5 per cent if 200 K.V. and 0.5 mm. Cu. are employed. The superiority of higher voltage for irradiation of this region seems self-evident.

The tendency to "local recurrence" may be diminished by wider resection of skin and fascia and meticulous care in the handling of carcinomatous tissues. Clinically inappreciable metastases in the supraclavicular and internal mammary region, however, are probably better handled by

radiotherapy. For this reason at present we prefer more vigorous dosage and higher voltages for postmastectomy roentgenotherapy.

In spite of the various shortcomings of repeated small low-voltage treatments, which we now recognize. This was the method of therapy in a series of 78 radical mastectomies treated at the Presbyterian Hospital, New York, from 1923 to 1929, and followed up for a minimum of five years. The technic consisted in the administration of 400 r over the operative chest wall and anterior surfaces of the adjoining axilla and supraclavicular regions, as well as the opposite axilla. The factors used were 130 K.V., 0.25 mm. Cu. plus 1 mm. Al. (= about 6 mm. Al.) and 40 cm. T.S.D. The series was repeated at least once, in four to eight weeks. In some cases additional similar cycles of treatment were given at two- or three-months intervals, several times more. Treatment in all of the cases had been started within six months after operation. All had been proven microscopically. Particular attention has been paid to clinical factors which might influence evaluation of this method of treatment in this series of cases.¹⁵

The age at which the tumor first made its appearance in the 78 cases, showed a predominance of the fifth decade:

20 to 30 years.....	2.5 per cent
31 to 40 years.....	25.7 per cent
41 to 50 years.....	42.3 per cent
51 to 60 years.....	19.2 per cent
61 to 70 years.....	7.8 per cent
71 to 80 years.....	2.5 per cent

The right breast was involved in 36 and the left in 42 cases.

The quadrants in which the tumor arose, were in order of their frequency:

Upper outer quadrant.....	39 cases (50.0 per cent)
Central part of breast.....	17 cases (21.8 per cent)
Upper inner quadrant.....	13 cases (16.6 per cent)
Lower inner quadrant.....	5 cases (6.4 per cent)
Lower outer quadrant.....	4 cases (5.1 per cent)

Microscopic examination failed to disclose axillary metastases in only 12 cases. Of the remaining 66, the lower axillary nodes alone were involved in 25, and the lower and upper in 41.

The relation of the site of the primary tumor to the presence of homolateral axillary metastases was investigated:

* Courtesy of Prof. Kenneth Cole, College of P. & S., Columbia University.

Lower outer quadrant.....	4 (100.0 per cent of 4 cases)
Central part of breast.....	15 (94.5 per cent of 16 cases)
Upper outer quadrant.....	34 (85.0 per cent of 40 cases)
Upper inner quadrant.....	10 (77.0 per cent of 13 cases)
Lower inner quadrant.....	3 (60.0 per cent of 5 cases)

The above table would lead one to believe that irradiation of the operated axilla is indicated irrespective of the quadrant of the breast in which the primary tumor arose. However, this is contradicted by a study of the postoperative occurrence of metastases in this region. It will be remembered that both axillae were irradiated similarly, yet of 12 cases with axillary metastases arising postoperatively, only one occurred on the operated side and 11 in the opposite axilla; in 2 others both axillae were involved. In other words, metastases appeared mainly where the nodes had not been removed, and irradiation did not prevent their appearance. The same fact was corroborated by examination of the postoperative occurrence of metastases in the supraclavicular region: There were 22 cases which presented themselves on the irradiated (mastectomy), side and only one in the opposite side; in 5 others both sides were involved. From these figures, one cannot conclude that roentgenotherapy, as given in this series, helped to prevent supraclavicular or axillary metastases. It would also seem that where a thorough axillary dissection has been made, irradiation of the operated axilla is not essential, but that larger doses are needed for the supraclavicular region on the operated side and over the opposite axilla.

The influence of the site of the primary tumor on the frequency of occurrence of postoperative supraclavicular metastases was studied. No metastases were found where the tumor arose in the lower quadrants. Thirty-five per cent of the tumors arising in the central portion of the breast, 36 per cent of those from the upper outer quadrant, and 46 per cent of cancers originating in the upper inner quadrant, gave rise to metastases in the supraclavicular region of the same side.

Postoperative metastases to the opposite axilla occurred most frequently in tumors arising in one of the lower quadrants.

The preoperative size of the primary tumor in the breast was noted. The cases were arbitrarily divided into 51, in which the diameter of the mass was roughly 5 cm. or less, and 27 in which it was more

than 5 cm. The relation between the size of this mass and the presence of axillary metastases was studied. Of 51 cases in which the lump was 5 cm. or smaller, axillary metastases were present in 78.5 per cent, and of 27, in which the lump was larger than 5 cm., axillary metastases were present in 96 per cent. It might be noted that 8 of 10 tumors with preoperative axillary metastases on the operated side, in which the primary tumor arose in the upper inner quadrant, were 5 cm. or smaller. Such rapid spread to the axilla was not seen in tumors arising in the other quadrants.

Fifteen cases were alive and well for more than five years after radical mastectomy. Though free from cancer, one of the 15 died nine years postoperatively from pneumonia, and another from pulmonary tuberculosis fifteen years postoperatively.

The size of the mass, the presence of axillary metastases, the quadrant from which the primary tumor arose, and the preoperative duration of the tumor were studied, in their relation to the survival period. Most deaths due to cancer occurred during the first three years postoperatively, the cases with tumors larger than 5 cm. showing a slightly higher death rate (55 per cent of 27), than those with smaller tumors (47 per cent of 51). A study of the cases clinically arrested for more than five years showed this difference more clearly: There were 12 cases (23.5 per cent) of 51 with tumors 5 cm. or less, and 3 (11 per cent) of 27, with tumors larger than 5 cm.

Survival was greatly influenced by the extent of axillary involvement.

DEATHS DUE TO CANCER DURING THE FIRST
3 YEARS POSTOPERATIVELY
42 CASES

Axillary glands not involved	1 case (8 per cent of 12 cases)
Involvement of lowermost nodes only	12 cases (45 per cent of 25 cases)
Involvement of upper and lower nodes	29 cases (71 per cent of 41 cases)

Definite significance could not be attached to the quadrant from which the primary tumor arose,²⁰ except that the fewest five-year survivals (1 of 17) were found in cases arising from the central portion of the breast.

QUADRANTS IN WHICH TUMOR AROSE, AXILLARY
METASTASES, AND SIZE OF TUMOR IN RELA-
TION TO 5-YEAR CLINICAL FREEDOM
FROM DISEASE

Quadrants	Total No. of cases 78	Clinically arrested cases 15	Axillary metastases	
			positive	negative
Lower outer.....	4	1 (25 per cent)	1	—
Upper outer.....	39	9 (23 per cent)	8*	1
Upper inner.....	13	3 (23 per cent)	1	2
Lower inner.....	5	1 (20 per cent)	—	1
Central	17	1 (6 per cent)	1	—

* Two of these tumors were larger than 5 cm.
Of the 15 tumors, 13 were 5 cm. or smaller.

The bearing of the preoperative duration of the tumor on prognosis was not clear. The slower growing tumors caused less severe symptoms; the patients therefore came to the surgeon later, but the post-operative course of their disease also seemed slower. Among 11 arrested "small" tumors there were four (15 per cent of 27) in which the tumor had been noted for six months or less preoperatively; five (31 per cent of 16 cases) had been evident from seven months to one year; and in two cases (25 per cent of 8) the tumor had been present from one to three years. Of the three "arrested" patients with "large" tumors, one gave a history of less than six months, another close to five years, and the third, twelve years prior to mastectomy.

CLINICAL FACTORS INFLUENCING SURVIVAL OF
PATIENTS WITH RADICAL MASTECTOMY AND
POSTOPERATIVE PROPHYLACTIC
ROENTGENOTHERAPY

No definite significance could be attached to site or preoperative duration of tumor, except that only one of 17 cases with central tumor survived 5 years.

A review of the various clinical factors influencing the course of the disease in this series reveals the difficulty of evaluating prophylactic roentgenotherapy following radical mastectomy without the detailed information mentioned above.

The technic of dividing dosage over a period of months and years has been shown by Regaud¹⁶ and his coworkers, to be ineffective for permanent arrest of cancer in general, and they have substituted for

it the intensive fractionated method known as Coutard's technic. In a personal communication, Coutard recently stated that for some years past he has occasionally been successful in arresting inoperable cancer of the breast by his method of treatment. This led us to apply modified principles of his treatment to prophylactic roentgenotherapy following mastectomy.

In an effort to place this more intensive method of postoperative roentgenotherapy for breast cancer on a sounder basis, we carried out the following investigation. We exposed eleven cases clinically diagnosed as cancer of the breast, to varying doses of intensive fractionated roentgenotherapy; three to seventy days later mastectomy was done and the breast sections were studied microscopically by Doctor V. K. Frantz. The factors used were 200 K.V., 8 M.A., 50 cm. T.S.D., filter, 2 mm. Cu. plus 1 mm. Al. in 7 cases, and 0.5 mm. Cu. plus 1 mm. Al. in 4 cases. One single field over the breast tumor was used and the irradiation given within a period usually not exceeding three weeks. It is realized that greater dosage could have been brought to bear on the tumor by cross-firing from various directions; but for the sake of simplicity of calculating the tumor dose, the single field seemed more desirable.

Interpretation of Table

The size of the mass has been recorded in the clinical measurements before treatment. This is because most of the laboratory measurements were on fixed specimens. In many of the tumors there was a diminution in size clinically, but the amount was often in dispute, and it is, of course, difficult to know what proportion of this shrinkage was due to change in the stroma and what part to actual destruction of tumor cells. In this connection one is reminded of the current hypothesis maintained by some radiologists that x-radiation influences the stroma more particularly, and radium the tumor cells. In comparing this short series with another of equal length where the treatment was by implantation of radium, we have found no evidence to support this view. It must also be remembered that until the tumors can be thoroughly studied histologically both before and after radiation, it is very hazardous to attribute any microscopic findings to the effect of radiation. All the degenerative changes observed, both in stroma and tumor cells, have been repeatedly seen in tumors which have not been radiated, and detailed comparative studies on the individual tumors must be made before one can speak with assurance on this point.

The dose is shown as the skin dose. We attempted to estimate the tissue dosage but the estimates of the size of the tumor and depth below the skin were too inaccurate.

No attempt has been made to classify the tumors morphologically. In the first place, there

is great variation in the morphology of tumors of the breast. Several careful studies in grading breast tumors according to the degree of malignancy have been made, but so far as we know the relation between definite morphologic types and radiosensitivity has as yet not been securely established for cancer of the breast. With a standard operative technique and a careful clinical follow up it should be possible to come to some conclusions about the relative malignancy of different types of tumors, but in order to estimate the radiosensitivity the same technique must be followed, that is there must be an adequate study of the tumor histologically before it has been radiated and a large enough series must be treated by uniform technique so that the five year follow up can be compared. This has not yet been done. It must also be remembered that not infrequently a single breast tumor may vary in morphology in different portions of the original growth, as well as in the metastases, although this is not the rule. Radiation may so alter the original morphology that it is no longer recognizable. This is suggested by one case in our series in which the tumor in the breast, which showed what we thought were pronounced radiation changes, looked quite anaplastic, while the metastasis in the axillary node, which did not show radiation changes was a glandular carcinoma with mucin in the cells.

In all the cases there were recognizable tumor cells. In most there were shadows of tumor cells, without nuclei obviously necrotic. In all there were degenerative changes in the stroma and vessels. The preservation of tumor cells, however, is not necessarily an index of viability. One might consider these cells so badly damaged that they would remain quiescent or, perhaps, locked in the altered stroma. Unfortunately, however, in only 4 of the cases was mitosis controlled while its presence, we believe, is evidence of life in the cell. These observations were made only after careful study, counting, if possible, at least 100 high power fields or, if the material was very limited, 1000 cells, and then reviewing all of the tumor.

The cases are too variable and too differently treated to make the follow up of much significance. Moreover, not much more than a year has elapsed since the operation. Three, however, have metastases which may, perhaps, have already taken place before the treatment. This seems

especially probable in one case which developed a mass in the opposite breast only two months postoperatively. The others were later and were bone metastases. It is noteworthy that as yet there have been no local recurrences. We do not know how one can decide where the credit for this goes—to the surgeon or to the radiotherapist.

Analysis of the above makes it questionable whether sufficient dosage for permanent arrest of hidden cancer cells can be administered without serious damage to normal tissues in the operative area. To obtain the tumor doses quoted above with the factors as described, it was necessary to produce a complete shedding of the epidermis of the irradiated skin in the cases receiving 3,000 r (in air) or more on the skin. The most striking case is the one where apparently intact cancer cells were found in the skin nodules²⁴ which received 3,400 r. Apparently viable cancer cells were found in all of the tumors examined, and mitoses were seen in 6. The interval between the last roentgen treatment and the mastectomy was in all but two instances sufficiently long to allow for a full effect of irradiation to take place. Though it is not denied that clinically these cases might have remained quiescent, this possibility is made unlikely in at least 5 cases by the presence of mitoses, 28 to 70 days after irradiation.

These findings do not, however, in the least militate against prophylactic postoperative roentgenotherapy for the purpose of restraining growth, of possible hidden metastases. That growth restraint is possible even with small doses was illustrated earlier by the case of cancer "en cuirasse" partially controlled for three and a half years and probably accounts for the reports of an increased number of five-year sur-

vivals of irradiated, as compared to non-irradiated mastectomy cases. It may be assumed, that cancer cells, like spirochetes in syphilis of the central nervous system, may lie dormant in the tissues until some factor in the tumor or host reactivates their growth so that their presence becomes clinically appreciable. This is illustrated by those occasional cases of skeletal metastases which do not manifest themselves clinically until fifteen or twenty years after mastectomy.^{18,19} As permanent arrest of hidden masses of cancer cells following mastectomy does not seem likely with the use of average doses of post-operative roentgenotherapy, the real function of this treatment should be to increase the tendency of the body to *restrain the growth* of cancer cells left behind after the operation. Five-year survivals form the basis of surgical statistics, yet breast cancer deaths occur after this period. Eight of the 78 cases in our series died of cancer later than five years after their treatment.

We believe that perhaps better growth restraint may be obtained by the use of more vigorous x-ray dosage. We have therefore, experimented with single series of 1,000 to 2,000 r (in air) to the anterior and posterior surfaces of the supraclavicular region of the same side, the anterior surface of the sternal region, and frequently to the posterior aspect of the operated axilla. We prefer 200 K.V. to the lower voltages for reasons stated earlier. Our observations, however, are as yet too few and too short, to permit correct evaluation of the merits of this method.

The material presented thus far leads to the following conclusions:

1. The survival period of 78 patients with radical mastectomy and postoperative medium voltage x-ray therapy was influenced by the pre-operative size of the tumor and extent of axillary metastases.

2. Cancer cells were found microscopically in 11 cases of carcinoma of the breast treated pre-operatively with doses ranging from 600 r to 3,400 r (in air) on the skin. It is unlikely that sufficient dosage is given in the usual course of postoperative x-ray therapy to completely destroy cancer cells hidden among the poorly nourished radiosensitive tissues of the mastectomy field. The function of postmastectomy roentgenotherapy at present, should be growth restraint, and careful clinical observation, continued for years after radiotherapy, should be part of this function. We are as yet uncertain as to the best method of applying roentgenotherapy for this purpose. However, single series of rigorous treatments, not

repeated, have in cancers of other regions been proven more efficient than weak doses repeated over periods of years.

3. Irradiation following radical mastectomy with thorough axillary dissection, should be concentrated on the supraclavicular area of the same side, the presternal region and perhaps opposite axilla.

4. High-voltage roentgenotherapy is probably preferable; especially for retrosternal nodes.

5. The danger of postirradiation pulmonary sclerosis with average doses is negligible.

180 FORT WASHINGTON AVE.

DISCUSSION

DR. DOUGLAS QUICK: Dr. Lenz and his associates have given us an admirable report on the postoperative therapy of breast cancer. It is a large field and one in which every member of

this Section doing therapy is vitally interested. The greater uniformity of agreement we may be able to arrive at on this subject the better will be the results. Good postoperative therapy of the breast is very necessary because many surgeons will not consult irradiation therapy until after their real interest in the case is terminated by the completion of their operation.

Personally I am more interested in preoperative irradiation of breast cancer, and irradiation alone in certain cases. It is my belief, supported by reasonable experience, that preoperative irradiation lends greater assurance to the ultimate result than does postoperative treatment alone. The reasons for this are rather well recognized

by radiologists and, hence, need not be enumerated here. It is my opinion that too many borderline cases are still being operated upon and then being turned to postoperative therapy with the false hope that this treatment will eventually remove the curse from the otherwise ill-advised operation. In the early days of irradiation therapy some of the major cancer groups had the advantage of strong men championing treatment by irradiation. I refer to work such as that of the late John G. Clark and the late H. H. Janeway in cancer of the cervix uteri cancer of the mouth. Today the treatment of cancer of the breast needs the aggressive support of similar advocates.

POVERTY AND DISEASE

The increasing toll of disease in the poorer sections of our cities can be remedied better by the provision of proper food and housing than by pouring millions into propaganda for health insurance, remarks the *New York Medical Week*, which is in a position to speak with considerable authority. With the prolongation of the depression, it says, there is mounting evidence that a large amount of ill health among the poorer classes is the product, not of an inequitable system of distributing medical care, as the advocates of compulsory health insurance would have us believe, but of the appalling living conditions that poverty imposes. Disease and death have their choicest stalking grounds in the overcrowded unsanitary tenements reserved for the poor. Welfare workers have found 33 per cent more illness among the jobless than among the gainfully employed. Not only is malnutrition, with its attendant susceptibility to respiratory infection, on the rise, but there is a marked and significant increase in the percentage and degree of the psychoneuroses springing from anxiety and fear.

There is indeed a vast need for preventive health service among the poor, but it is not as much a need for elaborate physical examinations of the able-bodied as for sanitary housing, suitable food, and regular occupation. Periodic health examinations are a sound practice, but the essential foundation for health is clean, airy homes, adequate nutrition, and the certainty of regular earnings. The foundations that are spending millions in propaganda for compulsory health insurance would be surprised at the improvement they could effect by devoting their resources to such practical uses as low-cost housing.

Through good times and bad, the health of the world has continued to improve steadily under the existing system of medical practice. The disproportionate ills of the poor and the lower middle class are due in large measure to their insecure economic status. Prevention lies in the eradication of poverty rather than the diversion of public funds to the costly bureaucracy on which compulsory health insurance rests.

AN EXAMPLE AND A WARNING

That is what the unhappy experience of the doctors of Milford, Mass., is called by the *New York Medical Week*, which found the matter reported in the *New York Sun*. As it remarks, Milford, which has strongly encouraged lodge practice in the past few years, is at once an example and a warning of what to expect if the physician loses his professional independence and becomes the servant of an employment organization. According to a recent editorial in the *Sun*, the practitioners retained by various fraternal groups in Milford received an annual fee ranging between eight and twelve hundred dollars a year, for which they were to treat members and their families for all ailments except those requiring hospitalization.

Here is the dream of the health insurance propagandist come true; the physician received a fixed (if obviously inadequate) stipend and the participating public reaches a new health level because of the opportunities for unlimited medical care. Alas, in Milford, as elsewhere, this has proven to be "such stuff as dreams are made of." In actuality, the community developed an acute hypochondria (or was it merely the

proverbial trading instinct of the Yankee) which kept the doctor busy at all hours of the day and night tending to minor discomforts for which a physician is not ordinarily called.

Milford is by no means alone in this experience. The patient of the lodge, contract, or insurance doctor is determined to get his money's worth; and the physician, no longer an independent practitioner but a hireling, is obligated to answer the summons of his employer at reasonable and unreasonable hours, for causes trivial or just.

In Milford the doctors are abandoning the fraternal organizations to regain their professional independence in private practice. Their experience is a warning to the rest of the profession not to fall in too easily with plausible schemes for lay control of healing.

The sage paragraph appears in the *Bulletin of the State Board of Health of Kentucky*, and is worth wide circulation: "Go to your doctor before he has to come to you. It is safer and cheaper."

CASE REPORT

A PROSTHESIS FOR EXENTERATED ORBIT

GUERNSEY FREY, M.D.

New York City

A woman of 44 had had a melanotic naevus of the left eyeball and lids for many years. It suddenly took on growth, became vascular, and showed every sign of malignant change. Exenteration of the orbit was performed, with removal of the lids. Secondary skin grafting was performed three weeks later, and the wound healed uneventfully. The pathological diagnosis was melanosarcoma.

coloring and life-like eyelashes give a very realistic effect. The device is held in place by spectacles to which it is attached by two thin wires—the shell frame of the glasses being in front of the line of junction of the skin and the prosthesis, and effectively concealing the artifice. Far from being grotesque or in any way disconcerting to the onlooker, the appearance of the patient wearing the prosthesis is extraordinarily

Fig. 1—The patient, after operation, without the prosthesis

Fig. 2—The patient wearing the prosthesis

Fig. 3—The prosthesis—front view

Fig. 4—The prosthesis—side view

The usual destiny of such cases is to go through life wearing a black patch over the deeply excavated orbit. To avoid this fate, this patient was referred to a well-known manufacturer for a prosthesis to cover the orbital aperture. A silver plate, modeled with beautifully moulded lids and globe, whose edges conform to the defect in the face, was provided. Artistic

natural. She has learned not to move the other eye, and when seen at a distance of three or four feet, the impartial observer is usually at a loss to decide which is the natural eye.

This case reminds us that when we have cases which are beyond the limits of plastic surgery, we may still resort to camouflage

CASE REPORTS

ACUTE PANCREATITIS COMPLICATING PREGNANCY

CHARLES R KINGSLEY, M D
St George Staten Island

Acute pancreatic disease during and after pregnancy is mentioned as a rarity in a few of our recent text books on obstetrics^{1 2} and reports have appeared only occasionally in medical literature

The following two cases are reported because so rare and violent a complication affected young, healthy women, because of the diagnostic difficulties, and finally because both patients recovered and both children lived In both the diagnosis was proven by operation

Mrs R B, gravida I, age 25, came under the writer's care September 14, 1932 The final day of her last menstruation was July 28, 1932, giving an expected date of labor May 5, 1933 Physical examination was negative, pelvic examination and measurements were normal Height 5 ft 7 in, weight 125 lb Urine was normal Past history and family history negative

With the exception of a gain of 41 lb in weight, pregnancy progressed uneventfully to term On April 10, 1933, blood pressure was 130/80, there was slight edema of the legs, a trace of albumin in the urine, the child in L.O.A. position, with the head well engaged On April 24th, the edema of the legs and thighs was considerable, but the albumin in the urine no greater and blood pressure 120/80

On April 27th, pains began at noon, colicky, severe, recurring at intervals of about fifteen minutes, and most intense in the epigastrium, back, and shoulders At 1 30 P M the face was flushed and she seemed anxious, complaining of the pains Abdominal palpation revealed no tenderness and the uterus seemed to contract with the pains Rectal examination showed a cervix neither dilated nor effaced but the head well engaged It seemed that typical labor had begun

At 4 40 P M pains had become more frequent, every ten minutes, across the upper abdomen Abdominal and rectal examinations were as before, but she had vomited twice She was taken to the Staten Island Hospital

In the hospital the pains became more severe until at 1 P M $\frac{1}{4}$ gr of morphine was given, though with but little relief An enema was ineffectual and vomiting had occurred again The blood pressure was unchanged, granular casts had appeared in the urine No evidence of progressive labor was found on rectal examination

On the morning of April 28th she was in great distress Pains had become almost continuous and she cried out with them, her face was drawn and flushed At 2 P M it was obvious that labor was not in progress but that some intra abdominal disaster was responsible for her condition The temperature was 101.4° F, pulse 120, respirations 36 Leucocytes were 23 600 with polymorphonuclears 93 per cent The abdomen was now tender but not rigid across the epi-

gastrium In both flanks there seemed some rigidity more marked in the right iliac fossa In consultation with Drs Charles E Pearson and Donald E Law a preoperative diagnosis of perforated appendix, perforated gastric or duodenal ulcer or high intestinal ileus was made Twelve hundred cc of 5 per cent glucose was given intravenously

At operation by Dr Pearson through a muscle-splitting incision there was a gush of turbid yellow fluid on opening the peritoneum The intestines were uniformly injected The appendix was normal Innumerable areas of fat necrosis studded the omentum and mesentery The diagnosis being settled it was thought best to decompress the abdomen Accordingly the writer performed, through a midline incision, a low classical cesarean section, delivering a living female child weighing 6 lb 7 oz

After uterine suture palpation revealed a normal gallbladder but a somewhat enlarged pancreas There was no mesenteric or retroperitoneal hemorrhage It was decided not to drain the pancreas in the belief that relief from intra-abdominal pressure might reestablish pancreatic function The midline incision was sutured and Dr Pearson performed a cecostomy before closing the first incision

A stormy postoperative course followed Although vomiting was absent and the cecostomy functioned well, there was abdominal distress for seven days, but at no time rigidity or marked tympanites T P R remained high On the 6th day a right lower pneumonia was found The cecostomy tube was removed on the thirteenth day Thrombophlebitis developed in the left leg with a further rise of temperature Defervescence was by lysis to normal on the twentieth day Repeated urinalyses showed albumin and granular casts and once $\frac{1}{2}$ per cent sugar, but the urine was normal on the 22nd day, when the patient left the hospital

Return to health was gradual Three months later, except for slight left leg edema, she was in good condition, urine, blood pressure normal, and without any disturbance of the gastro-intestinal tract One year later, May, 1934, mother and baby are both well

Mrs J B, gravida I, age 25 was suddenly stricken, February, 1918, during the third month of pregnancy with severe lancinating epigastric pain She fell to the floor Morphine was given by a nearby physician Several hours later she was seen by the writer still suffering severely She had vomited, enemata had been ineffectual Her face was pale and drawn, expression anxious, skin clammy, pulse 140, temperature subnormal The abdomen was flat, palpation well borne but there was some tenderness and rigidity in the

lower half. Because of pain vaginal examination gave little information.

She was removed to the Staten Island Hospital where the late Dr. William Bryan operated on the natural assumption that rupture of an ectopic pregnancy had occurred. A suprapubic midline incision showed the abdomen to contain considerable free bloody fluid. At first sight the pre-operative diagnosis seemed correct but search disclosed normal adnexae with a normal pregnant uterus of three months size. The incision was extended upward revealing mesenteries, omentum and retroperitoneal tissues distended with blood. The pancreas was tense and much enlarged. As the patient seemed in very poor condition with signs of impending collapse the abdomen was rapidly closed.

To our surprise this woman recovered, went on with her pregnancy and was delivered of a normal child August 29, 1918. Two years later she went through a normal pregnancy and labor.

Twelve cases have been found by the writer in the literature. Maertens³ collected 9 of these that had been reported between 1921 and 1928, the date of his report, one of which was his own. Kroger⁴, Gatewood⁵, Baker⁶, each reported a case. Of the 12, 3 recovered after operation. In several gallstones found either at operation or at autopsy were apparently the precursor of the pancreatitis.

100 CENTRAL AVENUE

PESTIFEROUS RADIO PRESCRIPTIONS

It is good news to many weary radio listeners to hear that the medical profession is trying to clear the air of the pestiferous patent-medicine peddlers. Heartfelt gratitude is voiced by Rollo Wells in a publication called the *Austinite*, where he remarks that it is time somebody headed off this epidemic of free advice which comes floating in every time we turn on the radio. Just as we get settled down comfortably to enjoy a hill-billy song, after tuning out a saw-filing soprano and a couple of gurgling crooners, the music stops and a sepulchral voice, accompanied by a clicking of loosely connected false teeth, reminds us that man born of woman is of few days and full of microbes.

Mr. Wells confesses that he gets a creepy sensation as this ethereal ghoul, between coughs, oratorically holds the gates ajar. Jitters pass up and down our handsome brow as he catalogues all of our private symptoms just like he was peeking through the keyhole, instead of talking a long way off.

When we are about to lapse into a state of coma, wondering if our life insurance premium

is paid, the radio medicine man tosses us a life preserver and we sit up and take notice.

He implores us not to die in the house, but to walk or limp to the nearest drug store and get a five-pound package of nature's own remedy, carefully compounded from an old Indian prescription.

Mr. Wells hopes the doctors are successful in their efforts to drive the radio medicine men back on the reservation and make them quit scaring us out of seven years growth every time we try to tune in the baseball scores.

If the doctors can't do that, they should at least make the radio medicine men stop playing the funeral march during their health talks. It's appropriate, but we break out with a rash every time we hear it.

A newspaper paragrapher proves that many a true word is spoken in jest when he remarks that, "a normal patient is one who waits five hours to call the doctor and then raves if he isn't there in ten minutes."

A GIRL WITH 200 TEETH

A Kansas City dentist was recently surprised to find that a young woman patient had 200 teeth in her mouth. As related in *Oral Hygiene*, the patient complained of toothache, and the dentist, on examination, noticed that she had a full-sized tooth growing in the roof of her mouth, but saw nothing else unusual.

Further exploration revealed, however, that every part of her mouth was sore. Unable to determine the cause of this sensitiveness, the dentist had roentgenograms made of her entire mouth.

Much to the amazement of Miss Larson and the dentist, these pictures when developed showed scores of tiny little teeth imbedded in the gums and roof of her mouth. These teeth were in addition to her normal set, but only the one in the roof of her mouth could be seen plainly.

To remove the extra teeth which ranged in size from a pin head to a grain of rice, required 200 extractions.

An effective home-made cooling system was devised during the hot spell last summer by three Nebraska doctors for their offices, as reported in the *Nebraska State Medical Journal*. Salvaging old car radiators, the three doctors set them up in their office rooms. Cold water from a tap passes through the radiators constantly. An electric fan is placed behind the cooling system and the cold air is circulated through the rooms. The room temperature is lowered from 20 to 30 degrees, they report.

What Ails Nursing?

This question comes home with great force to the doctor, the patient, the hospital, the quarter million trained nurses, and the thousands of young people who are looking hopefully to nursing for a career. What ails nursing? That is what a notable committee has been investigating in no less than eight years of study, and they have reached a radical and startling conclusion. Headed by Dr. William Darrach, the committee includes representatives of the American Medical Association, the American College of Surgeons, the American Hospital Association, the American Public Health Association, and three national organizations of nurses. Its conclusions, therefore, are well worth attention.

The verdict of the committee appears in a volume of 268 pages, entitled "Nursing Schools—Today and Tomorrow," and to put the 268 pages into one sentence, the committee finds that to-day we have too many nursing schools and that tomorrow we should close the doors of the largest part of them. In the words of the committee: "Overproduction in nursing has to be stopped. There is one way to stop it, and that is to close most of the training schools."

When we recall that there are no less than 1,583 of these schools in the United States, we can imagine the dismay that will strike many of them as they read this opinion of the committee. Few of us realize, perhaps, some of the facts stated in the report. One-half of all the schools of nursing in the United States, it appears, are conducted by hospitals with not more than 75 patients, while one-fourth of the hospitals have only from 8 to 42 patients, and this, too, in the face of the fact that a daily average presence of not less than 100 patients is the minimum set by the International Council of Nurses for hospitals with training schools, because, in their opinion, a smaller roster of patients does not afford an adequate variety of clinical experience.

These hundreds and hundreds of little schools, poorly staffed, poorly equipped, have flooded the country with a vast overplus of trained nurses who are conscientiously doing the best they know, but, through no fault of their own, do not know enough. The twin results, the committee finds, are "overproduction" and undereducation." That is what ails nursing.

Probing a little deeper into this unfortunate situation, the committee finds that it came about perfectly naturally. A few years ago the hospitals discovered that student nurses were greatly superior to the old-type untrained attendants for taking care of patients, and the slogan was raised: "The way to have good nursing is to have a school." So the schools blossomed out like the flowers in spring. The hospitals were glad to defray all the students' living expenses and to pay small monthly allowances in addition. Naturally the number of applicants, tempted by such terms, grew by leaps and bounds, and the number of graduates swelled in proportion. In 1900, there were less than 12,000 trained nurses in the United States; in 1930, there were over 280,000.

Right here the committee touches the sore spot. The aim of the hospitals was to secure the services of the student nurses. After their graduation they could shift for themselves. Every year a new crop of 25,000 trained nurses was released upon an already overcrowded market, so that even in the boom years of 1928 and 1929 the nurses had an acute problem of unemploy-

ment. It was a strange situation, unparalleled in any other vocation. "Suppose," says the committee, "that hospitals reserved all their medical practice for undergraduate medical students, and assumed that as soon as a student received his medical degree, he would take himself off to practice outside the hospital walls!" Yet that was the plan for the student nurses.

One remedy, as noted above, is "to close most of the training schools." The committee would have us no longer hold out the hand of invitation to the aspirant, only to tell her she is not wanted when she completes her course, but would have us staff our hospitals with graduate nurses, if it can be done without increasing the cost. And it seems that it can. Hospitals are finding that part of the work now done by students can be carried by maids whose salaries are low, that fewer graduate nurses than students are needed, and that the money spent on first-year students can better be applied toward graduate salaries. The movement of graduates back to the hospitals has, in fact, already started, and, if it continues, it will relieve the unemployment problem and make it easy for the hospitals to close schools that are not up to par.

The committee's report is of interest to all who are studying this problem, and many other bodies are doing so, including our own State Society. With so many able minds concentrated on the situation it can hardly be doubted that a solution will be found.

Some Dangers of Contract Medicine

A new form of contract practice, it appears, is springing up in various parts of the country, and has definite perils for the medical profession. Thus far it has been confined largely to the South, the West and the Southwest, but there is no reason for that matter why it should not invade any section of the land. For it is a child of the depression, and the depression, unluckily, is with us all.

Hard times drive the man of nimble wits into new fields, and some of these "hustlers" have been working in the West and South, trying to skin the dollars off from contract medical schemes. One of

these men will enter a city or county, stage a drive for members with canvassers, newspaper advertising and what not. "No more doctor bills to pay!" he advertises. "Relieve your mind of all worry for a total cost of five to eight cents a day. Full medical and surgical care, hospital maintenance, medicines, x-ray, dental work," etc., etc. When he has recruited his membership to a figure of several thousands, he approaches physicians who are feeling the pinch of hard times and easily builds up a staff of men tempted by the lure of stable incomes. What these men soon find, however, is that they are merely the hirelings of a business group, with a business manager, solicitor, adjuster, and advertising agent, all on the make, and taking the toll from both doctor and patient.

This is not a picture imagined by some alarmist, but is a factual account of what is now happening, related by Dr. Harry S. Nicholson, of Pittsburg, in an address before the Homeopathic Medical Society of Pennsylvania. The next chapter in the story comes naturally. Another hustler, envious of the success of the first, organizes a rival contract group in the same city at lower rates, and a rate-war begins, with the doctors of the two groups forced to make more and more calls at less and less pay. Jealousy, hostility, backbiting arise, good medical service becomes impossible, and the promoters sell out to anyone who will buy and leave to organize new groups elsewhere. Some of them may easily be now headed in this direction.

At the other end of the scale we have contract doctors employed by some of our largest and best corporations who have done splendid work in the investigations of industrial diseases and in maintaining the health of workers too careless to consult a physician until too late, if left to do it themselves.

Between the top and bottom of the scale we have many light and dark shades from the white to the black. Evil creeps in where commercialism becomes dominant. Today we see, in various parts of the country, contracting physicians, contracting groups, insurance companies, hospital associations, and all kinds of clinics with medical service to sell. There are said

to be 553 different insurance organizations furnishing hospital or medical services, or both, in the United States today. One doctor related, in the discussion following Dr. Nicholson's address, that at one time he signed up as doctor for a fraternal organization and found he was required to make as high as 40 calls a day, and, he remarked, "you can readily see that, making 40 calls a day, your attention to each family is practically nothing." After leaving this work to take up a practice of his own, he took occasion to look into the matter and found that the fraternal organization collected \$14 a year from each of its families, of which "one dollar goes to the doctor and \$13 go for maintenance and for putting up a million dollar organization."

A little analysis of the situation shows that the evils arise when lay management is in the saddle, trying to "work" the doctor to squeeze out the profits. That way lies ruin for the physician, for the patient, and eventually for the scheme itself. Only plans that keep the medical man his own master can endure.

Maladies of Musicians

It seems an irony of fate that those devoting their lives to producing harmonies for the pleasure of others should in the process afflict themselves with physical and psychic disharmonies that "by and by will make the music mute." The more successful the player or singer, the harder he must practice, the more he must use the delicate muscles, cords, nerves, that work in unison to make the concord of sweet sounds. If his violin string frays, he can put in a new one in two minutes, but if a muscle cramps, if a sore spot develops anywhere, he carries no spare parts for replacements. He must resort to his doctor, who then finds that he will do well to know something about the maladies of musicians.

Every town and city has its musical devotees, amateur and professional, and nearly every physician has one or more of these on his list, who may appeal to him for help at any time. Yet little has been published on this intriguing subject. Dr. J. Flesch, of Vienna, has written a book on "Berufskrankheiten des Musikers,"

and Dr. Kurt Singer, in this country, is the author of a work on "Diseases of the Musical Profession." A Maine physician, Dr. Samuel H. Kagan, has gleaned a number of facts from these books, and enriched them by interviews with professional musicians, to produce an entertaining and instructive article in the *Maine Medical Journal*. One of his informants is Dr. Harry Shilkert, of New York City, who is at the same time a doctor and an accomplished musician, and is well fitted to throw light on the subject.

No matter whether the musician produces his harmonies from strings, wind instruments, percussion instruments, or the delicate cord of his own voice, he is liable to find trouble. The violinist or the pianist feels his hands losing their skill, the singer finds that his larynx muscles no longer respond. The injury, too, may spread to inflame neighboring sheaths and tissues, and when one muscle balks from fatigue, others are called in to aid until they also overtire and the inflammation affects a wide area. The orchestra director finds that his hand and arm will no longer beat time, his legs cramp and lose their spring, and instead of inspiring his orchestra to flowing rhythms, he presents an awkward and pathetic figure.

The singer who has to perform in halls that are now chilly and drafty, now overheated and filled with tobacco smoke, who has to sleep on trains, snatch hasty meals of all kinds, and live the life of a high-grade tramp, will almost certainly pay the price in laryngitis and trouble with the vocal cords, such as "singer's nodule," or corn. Many of the singer's vocal ailments have a nervous basis and can be made worse by the very worry they cause, and made better by rest and mental calm.

The pianist often suffers from cramps due to the acute flexion of the wrists in playing octaves, especially when the wrists are weak. Ganglions of the wrist may result. "Apparently," remarks Dr. Kagan, "the family Bible is still used to rupture these swellings, from various comments heard." The old method of piano teaching, where the player sat with his body as stiff as a ramrod, led to fatigue, muscle pains, and cramps in the shoulders and spine, often misnamed "neuritis." In the modern method the body sways with the swing of

the hands up and down the keyboard, and the spine is relaxed.

Violinists, it seems, develop ganglion of the wrist from the acute flexion used, and the fingers and hands develop cramps, weakness, and paralysis. Not only are both hands liable to be affected, but the legs and shoulders may develop pain due to wrong posture, and too much inclination of the head, with severe overexertion of the neck and shoulder muscles, sometimes results in permanent torticollis. Pressure of the jaw on the violin may cause bruising and perhaps ulceration, and infection of the skin may arise from sensitivity and irritation from sweat. Bass violists, we are told, develop blisters, callouses, and tears of the skin of the fingers from the peculiar slap and plucking of the strings known as "jazz slap."

Cornetists and players of other wind instruments have affections of the lips and mouth, as will be readily understood. Blowing wind instruments is beneficial to the lungs, we are assured, except when the player already has tuberculosis; then "one should advise against the use of wind instruments, as it is the opposite of stabilization of the lungs." Trumpet playing, too, aggravates asthmatic conditions and so tends toward emphysema, which may result in incapacitation. Cases of otitis media may be exacerbated by wind instruments.

Accurate diagnosis, says Dr. Kagan, requires a thorough physical, neurological, and often psychological examination. Fatigue is usually due to faulty methods. Rest periods during practice are important. Reeducation of the muscles may be required. Massage, hydrotherapy, and active and passive exercises are useful. For acute pain and cramps, heat, as by diathermy, baths, lights, is of benefit. Medication is declared of little use, and electricity "is of questionable value." Dr. Kagan cautions against fat applications for the lips, as they cause the mouthpiece to slide about, which is serious. Surgery of the lips, too, should be avoided, as it may spoil the lips, even if it gets a perfect anatomical result, because of the neurosis established from worry and fear of inability to get notes.

It is easy to imagine the thrill of horror that stabs the soul of the musician when he feels a paralyzing cramp that threatens to halt his career, and it is a source of gratification to the physician when his skill can restore the power to create harmonies in a world where harmony is supremely needed.

PEDIATRICS

The coming Regional Conference of the Academy of Pediatrics and the Tri-City Pediatrics Group will be held on October 19 and 20, 1934, at the Hotel Ambassador in New York City and at the New York Hospital.

PROGRAM OF THE ANNUAL MEETING

FIRST DISTRICT BRANCH

MEDICAL SOCIETY OF THE STATE OF NEW YORK

The 28th annual meeting will be held on October 24, 1934, at the Forbush Inn, Peekskill, N. Y. This branch comprises the County Societies of Bronx, Dutchess-Putnam, New York, Orange, Richmond, Rockland, and Westchester.

THE PROGRAM

1. Address by the President of the Medical Society of the State of New York.....*Arthur J. Bedell, M.D., Albany*
2. Paper: "Medical Welfare Administration".....*Joseph S. Lawrence, M.D., Executive Officer of the Medical Society of the State of New York*
Discussion: *To be opened by James E. Sadlier, M.D., Chairman, Committee on Public Relations of the Medical Society of the State of New York*
To be continued by: Aaron Sobel, M.D., Dutchess-Putnam County; Terry M. Townsend, M.D., New York County; William C. Buntin, M.D., Richmond County; Morley T. Smith, M.D., Westchester County; Maurice A. Magid, M.D., Bronx County
3. Address*Amos O. Squire, M.D., Ossining*

ANNUAL MEETING OF THE THIRD DISTRICT BRANCH

On September 19, 1934 the Third District Branch of the Medical Society of the State of New York held its Annual Meeting at Livingston, New York, in the Potts Memorial Hospital, under chairmanship of the Branch President, Dr. Clark D. Rossman of Hudson.

About 77 members and guests were present, representing the seven counties that comprise this District Branch, Albany, Rensselaer, Schoharie, Greene, Columbia, Ulster, Sullivan.

In the forenoon there was presented a symposium on The Columbia County Department of Health as follows:—

Organization—

William D. Collins, M.D., Hudson; President, Columbia County Board of Health.

Relation to the Physician—

Frank C. Maxon, M.D., Chatham; President, Columbia County Medical Society.

A modification of the Detroit Plan in Administering Public Health—

Louis Van Hoesen, M.D., Hudson; Commissioner of the Columbia County Department of Health.

These three talks showed that a County Society and a County Department of Health can pool their knowledge, their thoughtfulness and their energies in harmonious fashion to preserve the health of the citizens of the County at its highest level. They will appear later in the JOURNAL.

Later Dr. Charles J. Hatfield, President of

the Potts Memorial Hospital and also Director of the Henry Phipps Institute for the Study, Treatment and Prevention of Tuberculosis of the University of Pennsylvania at Philadelphia gave a talk on Rehabilitation of the Tuberculous at the Potts Memorial Hospital. He gave a brief summary of the establishment of the Hospital and outlined its methods. Dr. Henry A. Pattison, Director of the Hospital, and Dr. Leonard M. Neisen, Resident Physician, described the work in the Hospital, gave histories of interesting cases, and exhibited both slides and patients.

After luncheon, Dr. Arthur J. Bedell, President of the Medical Society of the State of New York, addressed the Meeting, explaining the work of the House of Delegates, the Council and the Executive Committee. He earnestly endeavored to correct some erroneous ideas that seemed to be current as to the work of these bodies.

The annual election of officers for the ensuing year then took place with the following result:—

President:—Luther C. Payne, M.D., Liberty.

First Vice-President:—Augustus J. Hambrook, M.D., Troy.

Second Vice-President:—Bertram W. Gifford, M.D., Saugerties.

Secretary:—William M. Rapp, M.D., Catskill.

Treasurer:—Ernest E. Billings, M.D., Kingston.

ANNUAL MEETING OF THE FOURTH DISTRICT BRANCH

On September 21st and 22nd the Fourth District Branch of the Medical Society of the State of New York held its Annual Meeting at the Sir William Johnson Country Club in Gloversville, under the chairmanship of Dr. Raymond G. Perkins of Malone.

At the first session on September 21st the following papers were read:—

1. The Clinical Diagnosis of Surgical Diseases of the Abdomen, Edward M. Livingston, M.D., New York.

2. Obstetrical Practice in Northern New York, Edwin M. Jameson, M.D., Saranac Lake.

3. Intracranial Hemorrhage, Wardner D. Ayer, M.D., Syracuse.

In the evening, following the dinner given by the Fulton County Medical Society at the Sir William Johnson Club the meeting was addressed by the following speakers:—

Address of Welcome

Walter R. Grunewald, M.D., President, Fulton County Medical Society.

Arthur J. Bedell, Albany, President, The Medical Society of the State of New

York.

Thomas Parran, Jr., M.D., Commissioner of Health of New York State.

The second session was held on Saturday morning, September 22, 1934. The following papers were presented:—

1. Diseases of the Colon, Richard B. Catteil, M.D., Boston, Mass. (by invitation).

2. The significance of Hematuria, William J. Kennedy, M.D., Gloversville.

3. The Heart Muscle with Advancing Years, Herman O. Mosenthal, M.D., New York.

The election of officers resulted as follows:—

President:—Dr. John P. K. Cummings, Ticonderoga.

First Vice-President:—Dr. Carl R. Comstock, Saratoga.

Second Vice-President:—Dr. Sylvester C. Clemans, Gloversville.

Secretary:—Dr. E. Harrison Osterby, Amsterdam.

Treasurer:—Dr. Sidney F. Blanchet, Saranac Lake.

LORENZ J. BROSNAN, ESQ.

Counsel, Medical Society of the State of New York

Operation—Foreign Body—Responsibility of Surgeon

A short time ago a case came before the courts of one of the midwestern states, in which a decision was made upon a matter of great importance to the members of the medical profession.

The plaintiff in the case instituted a malpractice action against a surgeon who had performed an operation upon her. She claimed that the surgeon was negligent in permitting a laparotomy sponge to remain in her body subsequent to an abdominal operation. For a proper understanding of the case it is necessary to set forth in some detail the facts surrounding the case:

The defendant was a surgeon of considerable experience, having performed nearly one thousand major operations. The plaintiff consulted him concerning her condition and a diagnosis was made of appendicitis and a retroverted uterus. The surgeon advised operation and the following day he operated. In the performance of the operation he made use of the regular operating room staff of the hospital, which consisted of another doctor, an interne and several nurses. All of the said people were either connected with the staff of the hospital or were employed by it, and none of them were either directly or indirectly in the employ of the defendant. The duty of Dr. C., the assistant, was particularly to hold the retractors keeping the wound open and to hand instruments to the surgeon. The duty of nurse A. was to administer the anesthesia and to make records of sponge counts. The duty of nurse B. was to hand the sterile sponges to the operating surgeon, as needed, and to keep count of them. The duty of nurse C. was to keep track of, and dispose of the used sponges.

The defendant made a usual midline incision about six inches long, below the navel, and packed away the intestines with hot laparotomy sponges, after which he removed the appendix and performed an operation upon the uterus. After that

had been completed he inspected the field of the operation, saw all of the pads, checked up on the sponge count (which was announced as correct), and having no further occasion to explore the abdomen, closed the wound in the usual manner. During the operation approximately fifteen to twenty sponges had been used.

The patient did not make a good recovery from the operation and her complaints led, some months after the operation, to examinations which disclosed the presence of a foreign body. She was operated upon and a laparotomy sponge was found in, and removed from her abdomen.

Her case against the physician came on for trial and the plaintiff proved that the foreign body had remained in her person subsequent to the operation performed by the defendant. After both sides had introduced their testimony, the Trial Court sent the case to the jury and among the instructions which were left with the jury was the following: "The Court instructs the jury that a surgical operation begins when an opening is made into the body of the patient and ends when the opening has been closed. The removal of the sponges inserted by the surgeon is a part of the operation, and if the jury believed from the evidence that the defendant inserted and then negligently left a pad or sponge in the plaintiff's body, and if you further find from the evidence that the plaintiff thereby sustained damage, then the plaintiff is entitled to a recovery." Under that instruction the jury found, as seems to have been inevitable upon such an instruction, a large verdict in favor of the plaintiff. An appeal was taken from this judgment and the Appellate Court adopted a different view from that taken by the Trial Court, and reversed the judgment in favor of the plaintiff.

The Appellate Court, in reviewing the testimony, found that the following pro-

cedure had been followed at the hospital in dealing with the sponges that were used by surgeons performing operations such as the one in question:

"The sponges were made by the nurses at the hospital, counted, put up in packages, and sterilized. Laparotomy sponges are larger than the other sponges used, and are put in packages of three. The smaller sponges are put in packages of twelve. Before beginning an operation, the sponges are brought into the operating room by the nurses whose duty it is to handle clean sponges. They are counted by her, and as needed, are handed by her to the surgeon, forceps being first attached to the laparotomy sponges. As the sponges are used, they are thrown into a receptacle by the surgeon and taken charge of by a nurse, who places the small sponges in piles of twelve, and the used laparotomy sponges in piles of three. When the operation is finished, and before the incision is closed, the unused sponges are counted by the nurse in charge thereof, and the used sponges are counted by the other nurse. The total of the two counts is compared with the number brought into the operating room, in order to ascertain if all sponges are accounted for. The nurse in charge of the clean sponges announces whether or not the count is correct. If announced correct, the anesthetist immediately makes a written memorandum of the count on the operation record. This method was followed in full not only by the defendant, but by all surgeons operating at St. — Hospital and was used in the instant case. The small sponges are used to sponge up the blood and secretions and in operations upon the appendix or uterus the large pads, or laparotomy sponges, are placed in the abdomen, to keep back the mesentery, or contents of the abdomen."

The Appellate Court found that the testimony that had been introduced on behalf of the doctor had established that it was necessary to use sponges in the operation performed by him and that such sponges sometimes become soaked with blood and secretions and may have the general appearance of tissue and that they are not readily seen or felt and further

that in performing an operation such as was performed in this case the surgeon must think and act quickly and that it would jeopardize the life of the patient for the surgeon to take sole charge of counting the sponges and, therefore, of necessity, the counting of the sponges is a matter which must be delegated to the surgeon's assistants.

In deciding that under the circumstances presented in this case the defendant was not to be held liable in damages, the Appellate Court said:

"Notwithstanding the apparent care exercised by the nurse to make a correct count of the sponges, a mistake was made by one of them. It is immaterial which one made it. The crux of the case is whether or not the defendant is responsible for the mistake and can be mulcted in damages on account of it. . . . Generally an operating surgeon is not legally responsible for the mistake of a nurse in his employ where an operation is performed in a hospital not owned or controlled by the surgeon.

"All classes of hospitals have at least one power in common. It is the right to prescribe reasonable rules for the conduct of the institution and may standardize the hospital. The hospital was a charitable institution and maintained its own corps of nurses, internes and staff officers. A physician who used the operating room was required by the rules of the hospital to employ the equipment of the hospital. In the case of the particular operation, it included the nurses in attendance, the sponges supplied, and the records kept. Every physician who avails himself of the privilege of operating in a hospital of this character must conform to the rules of the hospital, and unless he does, he may be deprived of the privilege of practicing at that institution.

"Charitable hospitals being generally established through motives of philanthropy the right of admission rests solely in the discretion of the hospital authorities. No one has individually a right to demand admission. But if he is admitted, he impliedly consents to abide by the reasonable rules and regulations of the hospital, the same as his physician does.

"It is indisputable that the operation involved in this case was conducted, so far as the defendant's conduct was concerned, in strict accordance with the established rules and customs of the hospital. It is not denied that he endeavored to see that the rules of the institution concerning the count of sponges were carefully and correctly carried out. That a mistake was made by one of the nurses was no fault of his and appears to have been made in spite of his caution. He inquired about the count and was informed that it was correct. He made an ocular examination without discovering the error. He followed the approved method of examination unless it is known that a sponge is missing. Under all the circumstances we do not see how he could have been expected to do more."

This decision is an extremely fair one and is in harmony with the views recently expressed, in a similar situation, by the Court of Appeals of this State.

Claim of Improper Amputation of Fingers

A woman 29 years of age was injured in an automobile accident and brought into a hospital for emergency treatment. A surgeon was called in to attend her and found that she was suffering from severe injuries to her left hand. Her middle finger was practically amputated and the blood circulation was apparently cut off, and it was also badly lacerated, and her ring finger was similarly injured. The doctor told her that an immediate operation was necessary and that it was impossible to save the middle finger, and that she would have to leave it to his judgment as to what was best to be done with the

other injured finger. She consented, and an operation was performed under ether. On more careful examination the doctor found the middle finger practically amputated by the trauma of the accident at a point through the middle of the second phalanx, the second phalanx being fractured and the proximal phalanx being wide open. The finger was extensively lacerated on the palmar surface. The ring finger disclosed extensive lacerations on the palmar surface, compound fracture of the middle phalanx, both distal and proximal phalanx joints were opened up and the flexor tendon severed and partially destroyed. In the doctor's judgment the blood circulation in the ring finger had been so interfered with that unless he amputated the finger, gangrene would eventually develop. He accordingly amputated both said fingers and carefully resected anterior and posterior flaps in order to get smooth surfaces. He found it necessary to take several stitches in treating the patient's little finger. The patient made an uneventful recovery without infection, and left the hospital in five days after the operation.

Subsequently she brought an action against the surgeon in which she charged him with having amputated her fingers without her consent. She claimed that the damages which she sustained in the matter were especially great due to the fact that she was a stenographer. The case came on for trial before a Judge and a jury, and at the conclusion of the testimony the issues in the case were submitted to the jury.

A verdict was returned in favor of the defendant, thereby exonerating him of the plaintiff's charges in the matter.

X-RAY DEVELOPMENT

An x-ray apparatus which permits chest plates to be taken at as high a rate as 150 an hour at a cost as low as 30 cents each is described in the *New York Times*. The apparatus was invented by a New York City photo-engraver, in order to make cheaper chest plates available for public health work in tuberculosis. The Queensboro Tuberculosis and Health Association used the apparatus to x-ray 11,000 school children's chests, and the Bellevue-Yorkville

Health Center had 1,000 others done. The plates are of paper mounted in rolls. The entire apparatus is on a mobile truck.

A London comic weekly tells of a patient who said to his physician: "My wife tells me I talk in my sleep, doctor. What should I do?" To which the doctor replied: "Nothing that you shouldn't."

ACNEFORM ERUPTIONS

With Remarks on Acne Vulgaris and Its Pathogenesis

MARION B SULZBLRGER, M D, ADOLPH ROSTENBERG JR M D and J J SHER M D

From the Department of Dermatology and Syphilis of the New York Post Graduate Medical School and Hospital of Columbia University

Part I

PILOSEBACEOUS IRRITANTS, OBSERVATIONS IN ACNES OF KNOWN EXTERNAL AND INTERNAL ORIGIN, AND PARTICULARLY IN ACNES DUE TO HALOGEN INGESTION, FOLLICULAR ACNEFORM RESPONSES TO PATCH TESTS

As the follicle is frequently the primary site of the pathologic process in acne of known external etiology, in acnes in which internal administration of bromides and iodides is the eliciting cause, in acneform eruptions due to the products of the tubercle bacilli, and in the ordinary form of comedo acne or *acne vulgaris sive juvenilis*, it seems permissible to discuss these conditions as a group. Moreover, the choice of this grouping is motivated by certain analogies which will be the object of further discussion. The grouping is, of course, more or less arbitrary, with no intention of implying that the pathogenetic process underlying these forms is necessarily the same.

Among the external causes of acne, chlorine gas, tars, oils, waxes and greases are well known offenders. As prototypes of acne of external origin three recently observed cases may be cited.

Two young men and a young woman, all three without previous attacks of acne although in the acne ages (18, 23 and 27, respectively), all employed by the same firm and in the same kind of work, became suddenly afflicted with severe acne. These acne eruptions had begun within two months after the patients had commenced working at a job involving contact with hot oils and waxes, which not only touched the exposed parts of their skin, but also permeated their clothing. The patients

stated that, of approximately 100 other employees at the same work, over 40 were similarly and abruptly affected with the same form of acne dermatosis. The three patients we examined presented a classic but very severe widespread comedo acne of the face, forehead, cheeks, chest, and back, with papules, pustules, and cystic lesions (see Fig 1). Many lesions were also found in atypical localizations, on the arms, forearms, and thighs.

In spite of cessation of contact with the harmful agents (these patients did not return to work), and despite the most intensive treatment, the pathologic condition continued for an astonishingly long time (7 months, 1 year, and over 1 year, respectively).

At various sites and at varying intervals of time, patch tests performed on these patients, with the very waxes and greases with which they had come into contact, did not reproduce the acneform eruption, nor did they cause an eczematous response, nor in any way give evidence of a hypersensitivity of the skin to the materials applied.

These cases illustrate the clinical action of a substance with a capacity and a predilection for causing irritation of the pilosebaceous apparatus. Such a substance can produce the entire picture of a typical acne vulgaris eruption, including the comedo, papule, and pustule, the more cystic and deeper lesions, and the end result in characteristic pitted scarring.

These cases also demonstrate other important points. First, that the acne eruption may persist with surprising chronicity and refractoriness to therapy, even after the proven causative substance, and, second, that the application of a patch test, with

the actual causative agent of the acne, need not necessarily be successful in the experimental reproduction of the dermatosis.

The second group of acneform eruptions consists of those not due to pilosebaceous irritation from without, but to the hemogenous distribution of the pilosebaceous irritant. Bromides and iodides are well known causes of such eruptions. That these halogens (as well as other substances distributed by the blood stream) can cause acneform eruptions seems to be dependent, first upon the fact that the rich circinoid arrangement of blood vessels and the hemodynamic phenomena around the follicles are particularly conducive to a concentration of circulating substances at these

Tenchio.⁴) On the other hand, particularly in *acneform* eruptions due to halogens, we observed not infrequently a response to the patch test, not of diffuse and eczematous character, but distinctly follicular and acneform in appearance, closely reproducing the follicular acneform eruption from which the patient was suffering (Figs 2 and 3).

As far as we know, the observation of this *acneform* response to patch test in cases of acneform eruptions has not heretofore received attention. This form of reaction would seem to be of importance as an indication that a certain substance possesses a particular capacity for irritating the pilosebaceous apparatus of the

Fig 1—Acne due to external contacts with grease and oil.

sites (Jadassohn¹) second, that these halogens tend to be excreted through the sebaceous glands (R. O. Stein,² Kleeberg,³ and others); and third, that these substances, for some as yet unknown reason, seem to possess a special capacity for irritating the pilosebaceous apparatus.

As evidence of the existence of this third factor, it may be stated that during the last two years we have tested all our cases of bromo- and iododermas by means of patch tests, with ointments containing 25 and 50 per cent potassium iodide and potassium bromide, respectively. In several cases, the patch test produced an eczematous response of diffuse and non-follicular nature. (This, to a certain degree, confirms the findings of Bloch and

Fig 2—Acneform responses to patch tests with bromide and iodide on previously unaffected skin of chest of patient with acne vulgaris

patient, or, stated conversely, as evidence of a hypersusceptibility of the patient's pilosebaceous apparatus to the particular substance applied.

Two further observations seem of interest in this connection. The first is that chronic iodide and bromide acnes can be clinically almost indistinguishable from acne vulgaris (Fig. 3). We have seen such cases due to the chronic ingestion of iodized salt or to the very occasional use of bromides. The second observation is that, even in classic cases of acne vulgaris, in which it was impossible to elicit any

history of halogen ingestion, and which were in no way to be suspected of a drug etiology, bromides and iodides occasionally elicited an acneform and follicular response when applied by means of patch test (Fig. 2).

The third group of follicular and acneform eruptions, namely, those due to the hematogenous distribution of the tubercle bacillus and/or its products, would seem to have many similarities as far as the mechanism of their genesis is concerned, with the hematogenous halogen acnes. For example, lichen scrofulosorum, better called tuberculosis lichenoides, which is probably one of the most common forms of tuberculid, is characterized by its predilection for follicular localization.

Fig. 3.—Iodide acne closely resembling acne vulgaris. (Note acneform response to iodide patch test on chest.)

Furthermore, most dermatologists now agree that the tubercle bacillus and/or its products can, in certain exceptional cases, produce eruptions so closely simulating acne vulgaris that it is in some cases impossible to differentiate clinically between them.

A third type of acneform eruption of tuberculous etiology is one which is al-

most indistinguishable from acne rosacea, namely, that known as the *rosacea-like tuberculid of Lewandowsky*.^{*} (For a complete report on this form of tuberculid, see MacKee and Sulzberger.³)

The analogy between these tuberculous acnes and the halogen acnes is obvious. In the one case, the products of the tubercle bacillus, hematogenously distributed, selectively irritate the pilosebaceous apparatus. In the other case, the circulating halogen produces this effect.

At the Post Graduate Hospital, within the past four years, we have routinely tested a large number of patients (more than 100) with tuberculin patch tests. Many of the positive reactions to these

Fig. 4.—Acneform reaction to patch test with old tuberculin on previously unaffected skin of patient with acneform tuberculid. (Rosacea-like tuberculid.)

tests were of the follicular type. This form of reaction has been the rule, particularly in the *acneform tuberculids* and in lichen scrofulosorum (Fig. 5). The follicular response to tuberculin patch tests indicates that the statement made above, in regard to bromine and iodine, applies to tuberculin as well. For tuberculin would seem to be a substance possessing a particular capacity for irritating the pilosebaceous apparatus of certain individuals;

* The chronic use of iodides and bromides can produce not only acne vulgaris-like eruptions, but also clinical pictures resembling acne rosacea and rosacea-like tuberculid.

or, stated conversely, there is, in these individuals, a particular hypersusceptibility of the pilosebaceous apparatus to tuberculin.*

While the acneform eruptions discussed are not excessively rare, the fourth group, acne vulgaris, is of far greater frequency and, therefore, of far greater practical interest. Unfortunately, the present knowledge as to the pathogenesis of this condition is, to say the least, deplorably limited. The older theory of the bacterial etiology of acne vulgaris remains unproved and, to a great degree, discredited; the disease cannot be reproduced experimentally, in man or in animals, by means of the accused micro-organisms (Stein²). The newer theories dealing with the endocrine nature of the disease are vague and require crystallization and confirmation.

In view of this lack of knowledge, research into the cause of acne has lacked direction and guidance. It would, therefore, seem permissible and even desirable to suggest a working hypothesis which might prove of some value, if only in stimulating investigations along organized lines. From many hypotheses suggesting themselves, it seemed necessary to us to select *one* suitable for experimental investigation.

The hypothesis we have chosen includes the above outlined observations in acneform eruptions of known etiology, and it seeks to establish a common or related pathogenesis in acnes known to be of external causation, acnes known to be due to circulating hematogenous noxae, and acne juvenilis.

PART II

A WORKING HYPOTHESIS FOR THE STUDY OF ACNE VULGARIS

From the phylogenetic and ontogenetic points of view, the sebaceous glands and the hair follicles are to be considered invaginations of the surface epithelium. The cells of the hair bulb continue to undergo the same changes as those of the surface epithelium, namely, the changes of cornification; the sebaceous gland cells become differentiated in that they undergo not horny but fatty alteration, and these fatty cells form the secreta (holocrine secretion). It is obvious that an irritative

stimulus with a capacity and predilection for affecting the pilosebaceous apparatus may produce hyperactivity: (a) of the sebaceous gland; (b) of the hair bulb; and (c) of the follicle wall and the epidermis at the points where the invagination takes place. It is, in particular, the hyperactivity of the epidermis of the follicle mouth, which seems to play a leading rôle in the formation of the primary lesion of acne vulgaris, namely, the comedo. For, as Kyrle,⁴ Stein,² and others have shown, the first step in comedo formation is the epithelial irritation leading to *hyperkeratosis at the follicular mouth*, which gradually narrows the follicular orifice and finally forms a horny plug in the ostium. The hyperkeratosis and occlusion of the follicle, plus a hypersecretion of the simultaneously irritated gland, bring about the formation of the sebaceous and horny plug known as the comedone.

It is our opinion that variations in this mechanism may, in themselves, be sufficient to cause the entire picture of acne vulgaris and the accompanying (and frequently preceding) seborrhea. For one may have: (a) stimulation of seborrheic glands, with as yet unoccluded follicles, giving rise to seborrhea; (b) occluded follicles forming comedones (see Kyrle⁴); and (c) occluded follicles with hyperactive glands, in which the dammed-up secreta and any adjuvant substances coming from the circulation and excreted with the sebaceous material necessarily become concentrated.

This concentration of possible irritants and/or the mechanical irritation from pressure alone could, possibly, account completely for the subsequent lesions of papules, pustules, and abscess. It cannot be denied, however, that micro-organisms may play a rôle in the formation of the inflammatory and pyogenic development of the lesions. Such micro-organisms—as acne bacilli, staphylococci, micrococci, pityrosporon, bottle bacilli, demodex, etc.—not obligatory pathogens and normally found saprophytically on the skin and in the ostium of the follicle, become imprisoned within the follicle, under the horny plug. In this manner, these organisms may meet favorable conditions for growth and for the development of pathogenic activity in a follicle already damaged by stagnation and pressure. Or, the circulating substances may, in other ways, aid the pathogenic activity of bacteria (see Haxthausen, quoted by

* Similarly, trichophytin and oidiomycin patch tests are likely to produce follicular reactions.

Stein,²); or, on the other hand, the hypothetical substances may cause irritation only in follicles already abnormal, for instance, with anatomically deficient outlets. While these possibilities must naturally be considered, it does not seem to us that the action of the bacteria in acne can be primary; nor does our hypothesis necessitate the assumption of any bacterial activity whatsoever nor of any antecedent anatomic abnormalities. Both of these factors are unproved and would necessitate additional and complicating hypotheses.

If one sees as a primary cause of acne vulgaris a circulating substance or circulating substances with the capacity and predilection for stimulating, exciting, or irritating the pilosebaceous apparatus in certain predisposed individuals, it is obvious that close analogies exist between acne vulgaris and acneform eruptions due to the halogens and tuberculosis, and also those due to external pilosebaceous irritants.

It follows that one must look for the cause of acne vulgaris, either in the abnormal *quantitative or qualitative* presence of pilosebaceous stimulants or, in an abnormal susceptibility of the pilosebaceous apparatus to such stimulants, or in a combination of these factors.

In other words, to prove our hypothesis we must find either a substance or substances pathologically (quantitatively or qualitatively) present in acne vulgaris; or some substance or substances found and normally innocuous, but to which the pilosebaceous apparatus of acne patients can be shown to be hypersusceptible, or both.

Observations of the clinical course of acne vulgaris have naturally directed attention toward a certain group of possible causative agents. While acne vulgaris is practically unknown in infants and young children, it is an exceedingly common manifestation in the years immediately preceding sexual maturity and in early adolescence. A mild degree of acne is almost physiological in these years. Bruno Bloch⁷ examined 2,136 girls between the ages of six and eighteen years, and 2,055 boys between the ages of six and nineteen years. He found that comedones began to appear in these children between the ages of six and seven; and that, at the age of seventeen, 80 per cent of the girls had some degree of acne; and that, in boys, the condition developed earlier, so that, at thirteen years of age, 71 per cent of the boys were affected. He found, further-

more, a synchronous appearance of acne lesions and of pubic and axillary hair, and, in girls, of the first menstruation. These figures compose a statistical substantiation of the accepted clinical fact of the obvious connection between the awakening of the sexual endocrine activity and the appearance of acne vulgaris.

Bloch's findings showed not only that acne begins earlier in males, but that severe cases of acne were more than twice as common in boys as in girls, at nineteen years of age, there were 5 boys with severe acne to 2 girls with cases of equivalent severity. This finding fits in with our hypothesis. It would seem to indicate one of two things either, that the male possesses intrinsically a follicular apparatus more sensitive to hormonal stimulation, and with a greater capacity for reacting to such stimuli, or

Fig 5—Exacerbation of acne vulgaris after 48 hours of ingestion of moderate doses of KI. The face was practically clear before this medication.

that more hormonal pilosebaceous stimulants (irritants) may be formed in the male than in the female. The formation of the beard and the heavier body hairs in the male would tend to substantiate this concept. True eunuchs, that is, those emasculated before puberty, generally have no beards or very sparse beards, and their growth of secondary sexual hair is likely to be of the female type. It has further been established that true eunuchs do not become bald. (In the 340 eunuchs examined, no sign of seborrheic alopecia could be found—Sabouraud⁹). This observation seems to us to be of primary importance and can perhaps be explained in accordance with the theory that the male type of baldness is, in some way, the result of repeated overstimulation of the pilosebaceous apparatus of the scalp (see Hebra, Kaposi, Riehl, and others quoted by R. O. Stein,² page 62),

and that this overstimulation is, in turn, dependent upon male gonad activity.

There are yet other observations in acne vulgaris, which point to the circulating products of endocrine glands as being, in some manner closely connected with the development of the disease. There are numerous reports dealing with this subject. In this country, L. Hollander¹⁰ and Schamberg,¹¹ among others, have called attention to observations suggesting such a connection. More recently, Kurzrock and Rosenthal¹² reported that the urinary excretion of estrin was subnormal in women suffering from acne. It is frequently observed that acnes exacerbate cyclically in connection with the menses; and that some cases are combined with dysmenorrhea. The acnes of older women (chin acnes, etc.) appear in a preclimateric manner, at the time when there is, according to endocrinologists, not infrequently a terminal endocrine dysfunction. Pregnancy often affects the pilosebaceous apparatus; and the influence of the pregnancy upon the acne dermatosis, as well as upon seborrheic conditions, may sometimes be apparent. Just as acne vulgaris does not occur before the beginning of sexual activity, so also the disease does not exist in the aged.

In view of all these considerations, it seems a logical conclusion that the products of the gonads and/or of other endocrine glands in which there is increased or altered activity at the time of puberty, of pregnancy, and of menopause, either directly or indirectly contribute to the stimulation of the pilosebaceous apparatus; this stimulus physiologically produces the beard and the secondary sexual hair; and, in some cases pathologically, the formation of the comedo, and thus lays the foundation for acne. (Not only the sebaceous glands undergo such hormonal stimuli, but the embryologically related apocrine glands and the mammary glands of the female are synchronously and similarly stimulated.)

According to the concept outlined, acne vulgaris (and seborrhea and baldness, which are so frequently and familiarly associated with this dermatosis) would seem to be based upon an aberration in the normal and physiological process of hormonal pilosebaceous stimulation.

There are certain guides which can be used in the search for the hormone or hormones which may be actively engaged

in the stimulation of the pilosebaceous apparatus. During the last months of intra-uterine life, there is a marked stimulation of the epithelium and particularly of the hair bulb and the sebaceous glands, which leads, as is well-known, to the formation of the vernix caseosa and the lanugo hair of the fetus. This hyperactivity ceases with birth, and both the vernix caseosa and the physiologic hyperkeratosis of the newborn rapidly disappear.

At first glance, it may appear to be no more than a chain of remarkable coincidences that the stimulation of the fetal pilosebaceous apparatus (vernix caseosa and lanugo hair) should occur at precisely the time when the maternal, and probably also the fetal, circulation contain the highest level of certain sexual hormones (*e.g.*, prolans, estrin); and that the hyperactivity of the pilosebaceous apparatus should cease abruptly when the infant is cut off from its supply of maternal hormones; and that there should be a renewed hyperactivity on the part of the pilosebaceous apparatus at precisely the time when the individual begins to produce his own sexual hormones. But this chain of events ceases to be merely an extraordinary coincidence, and becomes a basis for experimental investigation, when one hypothesizes the direct or indirect causal relationship between the hormones and the stimulation of the pilosebaceous apparatus.

Part III

PRELIMINARY EXPERIMENTAL REPORT

Two possible modes of approach presented themselves for experimentation along the lines of our hypothesis. The first, to attempt to demonstrate, in cases of acne vulgaris, a pathologic quantitative or qualitative hormonal aberration, particularly in regard to the hormonal content of the blood stream, the skin, and the pilosebaceous apparatus. The second, to attempt to demonstrate a hypersusceptibility of the pilosebaceous apparatus of acne patients, directed toward normal hormones or their derivatives or constituents.

We have chosen to begin with the second of these approaches. It seemed possible that increased thyroid activity, frequently coincidental with increased gonad activity and leading to increase in circulating thyroxin (the iodine-containing hormone), might explain acne vulgaris as essentially of the same nature as a very chronic iodide

acne. To investigate this possibility, patch tests with both thyroxin and iodide ointments were applied in the usual manner in 75 cases of acne vulgaris. None of these cases reacted to the thyroxin test, and only 4 reacted to the iodide. However, in these 4, the patch test produced typical and persistent lesions in the previously unaffected areas to which the iodide test had been applied (see Fig. 2). This number of positive reactors even to strong (50 per cent) potassium iodide tests is too small to be considered as strengthening the possibility that acne vulgaris is essentially a modified iodide acne (thyroxin-derivative acne).

Nevertheless, before coming to the conclusion that these results entirely contradict the possible rôle of iodine compounds in acne vulgaris, a continuation of experiments and modifications of technic seem indicated. This is particularly apparent when one remembers that many true iodide and bromide acnes do not necessarily give positive reactions to iodide patch tests; and that even in cases of acne due to external irritants, we were unable to elicit a positive reaction by means of the patch test application of the causative substances.

In a second series of experiments, we attempted to study the possible effect of iodides in acne vulgaris, not by external application of patch tests, but by ingestion and hematogenous distribution to the skin and pilosebaceous apparatus. In 20 cases of moderately severe acne vulgaris, in which there was no history of halogen ingestion, and in 21 control individuals (persons without acne), potassium iodide was given by mouth and in moderate doses (3 teaspoonfuls daily during two weeks, of the following: potassium iodide, 10.0 in aqua, qs. ad 120.0).

In 20, i.e., 100 per cent of the acne vulgaris cases, the ingestion of iodide as prescribed caused, after 2 to 3 days, distinct exacerbations of the dermatosis, with the formation of many new lesions, and flare-ups of existing ones. (See Fig. 5.) In some cases, only previously affected areas, i.e., the typical acne sites, were affected; in others, a few acne lesions appeared in previously unaffected sites and in atypical localizations, for instance, on the forearms, buttocks, etc. (It seems noteworthy that these patients had all had negative patch tests to iodine in various forms. In some of them, such patch tests, repeated after the appearance of the exacerbation caused by

KI ingestion, still failed to elicit a positive response.)

In only one of the 21 control cases did the administration of this amount of the iodide produce acne lesions; and in this one, only two small papules appeared on the forehead after two weeks of the iodide medication (the patient stated that he had had similar lesions in the past).

This experiment shows that patients with acne vulgaris differ from the norm in their reaction to iodides; and that their pilosebaceous apparatus is pathologically hypersusceptible to the direct or indirect effects of the drug. 1. *It is impossible to interpret this finding or, at present, to discuss the possible relationship of the demonstrable iodide hypersensitivity to the actual causative factors in acne vulgaris.* 2. *But this clinical fact remains: relatively small quantities of ingested iodides regularly produce new lesions and exacerbations of acne in acne patients.*

It was a logical consequence to the above results to have the third investigative measure consist in the attempt to treat acne vulgaris as though it were actually an iodide or bromide acne; and to see whether the results of this therapy would be sufficiently favorable to serve as a therapeutic test. The therapy consisted in the administration of sodium chloride by mouth. We prescribed this in a form which we have found very effective in the treatment of iododerma and bromoderma, and which we believe to be superior to other methods of sodium chloride administration in these dermatoses. The patient is instructed to take 16 gm. of sodium chloride daily, in addition to the normal intake; administered in the form of 1 gm. enteric-coated sodium chloride tablets, as prepared for us and now marketed by Eli Lilly Co. The results of this therapy were extremely gratifying in a few cases, but on the whole did not produce the rapid amelioration so frequently seen in true iodide and bromide acnes. *The number of cases reacting favorably is too small for us to consider these results as proof of the possibility that acne vulgaris is a modified iodide acne.*

It must be remembered, however, that acne may persist for a very long time, even after the cessation of the action of the eliciting agents. This is shown, for example, by the persistence of the cases of acne of external cause for long periods

after cessation of contact with the eliciting agent. (See Part I.)

The next series of experiments was performed to determine whether or not acne vulgaris patients possess a pilosebaceous hypersusceptibility to various hormones other than thyroxin, and to substances other than iodides.* For this purpose, we carried out patch tests in the usual manner, employing the following hormones and other substances on a series of 39 acne patients:

- (1) Potassium iodide 5 per cent in aqua dest., later replaced by KI 25 per cent in aqua dest.
- (2) Potassium iodide 5 per cent in lanolin, later replaced by KI 25 per cent in lanolin.
- (3) Lanolin.
- (4) Thyroxin, 1:1,000, in aqua dest.
- (5) Parathormone.
- (6) Acne vaccine (Parke Davis Co.'s combined).
- (7) Antuitrin S.
- (8) Follutein.
- (9) Amniotin.
- (10) Theelin.
- (11) Antuitrin.
- (12) Pituitrin.
- (13) Glucose 10 per cent in aqua dest.
- (14) Syrup. simplex.
- (15) Lugol's solution, 50 per cent.
- (16) Chocolate in lanolin.
- (17) Chocolate in talc.

All of these tests were negative. It must again be stated that we do not consider the negative results of these relatively few experiments as conclusive. Continuation and modification of method is here necessary. It is to be pointed out, in particular, that our list of hormones is incomplete: for example, no experiments were undertaken with progestin and intermedin. Furthermore, the solutions employed may have been too dilute, or possibly even too concentrated. In these experiments we were limited to the employment of the commercially available concentrations. It would seem desirable to repeat these experiments, and especially with stronger solutions.

It should also be remembered that the action of hematogenously distributed hormones may differ radically from that of externally applied hormones. Such a

difference in the action of hematogenously distributed and externally applied substances is the rule in many forms of drug eruptions, in which the external application or the injection into the skin frequently produces no reaction, while the ingestion even of small quantities of the same drug produces the dermatosis. This difference in reaction to externally applied and to ingested iodide has been demonstrated in the reported experiments in acne vulgaris. Such differences in reaction, though unexplained, are frequently encountered. The same difference of action of iodides may often be seen in *dermatitis herpetiformis*. In this disease the internal administration of iodides causes a high percentage of exacerbations of the dermatosis, while the patch test application elicits a decidedly lower percentage of positive reactions.

Unfortunately, and for obvious reasons, no attempt could, as yet, be made to study the possible effects of the internal administration of the hormones which were employed in patch-testing the acne patients.

In closing, we should like to point out that our hypothesis speaks not against, but rather in favor of the correctness of the clinical observation that certain cases of acne are harmed or even produced by drugs and foods, such as, for instance, iodides, chocolate, cheese, milk, etc. (See, for instance, Cleveland White.¹³) Perhaps substances other than hormones, for example, other metabolites, may play a rôle. For, if the follicular apparatus in an individual tends to become hypersensitive, such a hypersensitivity may be directed not to hormones, but to other substances; or, the existing hypersensitivity may become polyvalent and embrace in its scope other substances as well. Nor, as we have said above, do we wish to exclude absolutely the possibility that bacterial action enters into the pathogenesis of acne vulgaris; for the follicle and gland, first stimulated by hormonal or other influences, may then become more easily susceptible to bacterial noxae.

Furthermore, the beneficial effects of the best available modern acne treatment, namely, x-ray and desquamating procedures, obviously counteract the pathologic occurrences which we have outlined. The x-rays, by reducing the activity of the hyperstimulated gland and follicle orifice; and the desquamating measures, by removing the obstructive horny plug. These measures are still those of choice.

* Perhaps even more fully than thyroid hormone, theelin and the chemically related male sex hormone would fulfill many of the requirements of our hypothesis, e.g., (a) present in both sexes; (b) increase at the end of pregnancy; (c) varying amount secreted at different phases of the menstrual cycle; (d) absent in castrates; (e) promote cornification (vagina).

in acne therapy. Fortunately, excellent results may be obtained through their employment in the majority of cases of acne vulgaris. Where they fail, the sodium chloride treatment will occasionally bring success. Prolan injections will help in a certain number of acne patients. And other methods will help in yet other cases. However, a certain number still resist every known form of treatment.

It is to be hoped that a clearer understanding of the seemingly basic endocrinologic phenomena involved will lead, in the near future, to a more causal and effective therapy of acne vulgaris, and perhaps even to new and adequate methods for combating the closely related seborrheas and seborrheic alopecias.¹⁴

DISCUSSION

DR. HERMAN SHARLIT. While we find it necessary to dissent from the validity of Dr. Sulzberger and his collaborators' procedures and the soundness of their hypothesis, we are indebted to them for a fairly complete selection of the clinical facts from which to discuss their hypothesis pro and con.

They point out that acne like papules occur (1) from the exposure to external irritants (greases) (2) the ingestion of iodides and bromides and (3) the toxins of tuberculosis, and while conceding that all these follicular

papules are not identical with those of acne vulgaris, they all represent pathology about the same anatomical structures. And without expressly saying so, they are accepting a sameness about all these lesions in terms of the function of these structures, hence, their reference to pilosebaceous apparatus, a functioning unit, not an anatomical one. The pilosebaceous apparatus in man is a vestigial organ harking back to the day when we were completely covered with hair. We have several million such units now feebly functioning to cover us with hair. Briefly, it is a hair root and a hair channel lined by modified skin and lubricated by an oil from a parenchymatous secreting organ emptying its sebum into this channel. It functions in response to stimulation like other organs and, like them, is exposed to overstimulation, understimulation, and mistimulation (irritation). But before considering the effects of stimuli on the pilosebaceous apparatus, we must thoroughly appreciate the prime importance of anatomical fitness to function. The follicular canal must be smoothly lined and the oil effectively lubricating. Grease rubbed into the follicular openings may readily destroy the anatomical fitness to function and under stimulation evidence this disability by the evolution of an inflammatory reaction the papule. Ingested iodine is stored in the skin and excreted in the hair in excessive quantities these are tissue irritants causing inflammatory reactions wherever they lodge. Iodides and bromides can produce not only follicular papules but destructive lesions of large areas of skin. The circulating toxins of tuberculosis do not limit their irritating action to follicles necessarily, other and bigger lesions of skin have been attributed to this species of irritation. All these circumstances are but evidences of anatomical change due to local irritation resulting in structural unfitness and emphasized and exaggerated in that unfitness in the presence of normal stimulation to the apparatus to function. None of this is evidence of any special irritability of the pilosebaceous apparatus for these substances, nor of unusual affinity of these substances for this apparatus.

It must be conceded that no known external irritant or circulating foreign substance is responsible for acne vulgaris and that the condition so uniformly appears synchronously with the maturity of sex function that it seems reasonable to suppose that the organism elaborates at about that time a substance or substances that operate, on the one hand to influence the sex organs and on the other the pilosebaceous apparatus (a secondary sex factor). And with the throwing into the circulation of this pilosebaceous "stimulant" acne appears. To me this is reasonable physiology and in keeping with clinical facts. Dr. Sulzberger and his collaborators accept this statement of the situation but in terms of their hypothesis see in this elaborated stimulant a basis for the acne to them this substance or substances probably elaborated by the glands of internal secretion have a perverted influence upon the pilosebaceous apparatus to the extent that these substances are irritants and may produce acne after the fashion of iodides tuberculosis toxins, and grease. We know of no substantiating evidence for this and cannot accept it. To us the explanation is as simple as when grease locally applied is the cause of acne,

namely, that the anatomically unfit follicular units (reflect on the comedone and its relationship to acne vulgaris), when put under the impetus to function, show their unfitness by a follicular papular reaction.

Our essayists undertook to test clinically their hypothesis by the use of the patch test. Of slight moment is the fact that these tests were all substantially negative. I am willing to assume that they were all positive, that they all produced follicular papules, and under these circumstances they would prove nothing with respect to their hypothesis concerning the pathogenesis of acne vulgaris, to wit, that the body elaborated stimuli to pilosebaceous apparatus circulating as specific irritants to set in motion the chain of events leading to the follicular papule. May I say in closing that the difference in the points of view of our essayists and ourselves may appear in the following analogy: A moving automobile is losing oil from its crank case and finally the motor breaks down. Our essayists say that the damage was done by the presence of gasoline in the gas tank, because if there were no gas in the tank the car could not move, and if the car were not moving the motor would not have broken. We say, in our simple way, perhaps, that the trouble resulted from the loss of the oil and that using the gasoline to drive the car was one way to show that the car was unfit for use.

DR. MARION B. SULZBERGER: I believe that Dr. Sharlit and I are in practically complete agreement, except perhaps on one point. I, of course, grant that the acne lesions appear in follicles which are in some way aberrant or altered at the moment at which the stimulant begins to act. However, it is a question in my mind as to whether this aberration is as simple as Dr. Sharlit imagines, and consists simply in

a nevoid abnormality in the excretory passage. There are many facts which speak against this assumption (for it must be still regarded as a pure assumption, there being absolutely no proof of the preëxistence of such an anatomic abnormality in the follicles of acne patients; clinical and histologic evidence both speak against this).

Furthermore, should there be a preëxisting and predisposing anatomic or functional abnormality, the stimulus which produces the acne eruption in these follicles would still have to be considered part of the pathogenetic process; just as for instance, phenolphthalein ingestion and distribution must be considered as part of the pathogenetic mechanism in the production of a phenolphthalein dermatosis, which subsequently appears in apparently normal, but certainly in some way predisposed area of the skin. To use Dr. Sharlit's parable of the automobile, let us assume that an automobile is defective in some way, just as the follicle may be defective in some way. We have, in the case of the follicle, no way of discovering its defect and no way of repairing it. This may be the case in a defective automobile as well. The automobile is capable of functioning provided it is not overloaded or driven too quickly, just as the follicle is capable of functioning and does not become the seat of the pathologic process unless it and the sebaceous gland become stimulated beyond the point of tolerance (speed and overload).

The best way to keep the automobile in the story from breaking down is to prevent its being overloaded or driven at an excessive speed. Similarly we are trying to ascertain what hormones or substances bring about the overloading of the follicle and the excessive sebaceous secretion and thus perhaps learn to prevent or counteract this factor.

PRACTICE IN A PENITENTIARY

The problem of the prison doctor in Sing Sing, it appears, is to keep the well from pushing their way into the hospital, for anywhere from 100 to 150 show up each morning for sick call, out of an average of 2,600 convicts, lured by the prospect of better food, more comfort, and surcease from work. Dr. Charles C. Sweet tells about it in *Medical Economics*. As a matter of fact, the doctor assures us, prison life is good for the convict and thanks not only to the medical care that they receive but to the enforced regularity of their lives as regards exercise, eating, and hours of sleep, most prisoners improve remarkably in health within two or three months after coming to Sing Sing.

A picturesque figure is the hospital artist. This man, a negro and a lifer, says Dr. Sweet, is present at every operation. At a point where the pathological feature of the case is most clearly revealed, the operation is halted for a few seconds while he makes a pencil sketch and gets an accurate mental image of that field. Afterwards, in his office the final touches are

put to the picture, and the completed pen drawing is filed with the patient's chart. These picture records, in color, are not only interesting but extremely valuable as part of the surgical records.

Whenever it is necessary to do a blood transfusion, donors are always chosen from among the prison population. The evening before the transfusion is to be made, an announcement goes out on the institution's radio that blood donors are going to be needed. The men get this message in their cells, and the next morning invariably a great number of volunteers show up at the hospital to have their blood typed. As many as three hundred men have appeared at one time in response to such a request, despite the fact that it is usually necessary to test four or five before finding a suitable donor. The one selected stays in the hospital that day and that night, and gets as his only special reward a chicken dinner, which he probably shares with somebody in the ward, perhaps the man to whom he has just given part of his own blood.

FURTHER COMMENTS ON HEAD INJURY — THE POSTCONCUSSION SYNDROME

NATHAN SAVITSKY, M. D.
New York City

The controversy still rages about the nature and significance of subjective syndromes following head injuries. The increasing social significance of the problem has again brought this vital subject to the foreground. A cool appraisal of the clinical material is often made impossible by the fact that investigators are too often polemical in their tone and point of view and seem to be defending or attacking some position or body of doctrine. An attempt must be made to evaluate the issues involved in an unprejudiced manner.

Among the varied syndromes following head trauma, there exists a group of cases which are considered by many entirely functional and psychogenic, but which should be unquestionably classed as organic, the sequel of intracranial injury.

It is evident that psychogenic reactions following head injury are frequent and that in many of these cases the desire for compensation plays an important role. In a later communication a more detailed study of these psychogenic symptom complexes will be presented.³⁰ Dr. Strauss and the author have been erroneously quoted as saying that all the so-called post-traumatic neuroses have an organic basis. In a previous study it was stated that there exists a group of cases following head injury which are usually included in the traumatic neuroses, but which are undoubtedly organic in nature. Whether this group is large or small is difficult to state at the present and statistical data must await further clinical studies.

The author's attention is confined entirely to the subject of head injury. The sequelae of head blows are different from the consequences of trauma to other parts of the body. One lamentable source of confusion is this persistent failure to distinguish between these types of injury.

In the usual trauma to the head in civil practice there is an absence of initial terror and fright which so many recent writers have stressed as a probable explanation of the clinical changes following injury.

The term traumatic neurosis includes a great many conditions of varied etiology. Coined by Oppenheim,³ it has outgrown

its usefulness as a convenient rubric for the classification of all kinds of sequelae not evidently organic. Friedman,⁴ in 1892, Horn,⁵ in 1916, Krisch,⁶ in 1927, Luigi,⁷ in 1933, and many others have emphasized the necessity of a separate consideration of a group of cases organic in nature and usually considered among the so-called traumatic neuroses. These cases present clinically a subjective syndrome without gross focal signs. A useful term to designate this group of cases is the "postconcussion syndrome." It is really a form of traumatic encephalopathy, using this term to designate all organic intracranial changes following head injuries including reversible physiological perversions of function.

Concussion remains to this day an unclear term. This word has been used for about 600 years by almost all writers on the subject. The most widely accepted definition of this term was that of clinical changes resulting from a head blow, without evident damage to the brain (Boirel,⁸ 1674). Up to 1839, so-called violent concussion included laceration of the brain. It was then that Dupuytren definitely distinguished between contusion and concussion of the brain. When Littré,⁹ in 1705, formulated his famous conception of concussion, he lived at a time when the microscopic changes in the intracranial tissues following head injury were unknown (recently summarized by Courville and Rand¹⁰). Petit, early in the eighteenth century, who ascribed concussion to the vibrations transmitted to the brain, knew nothing of microscopic pathology. Nela-ton¹¹ in 1855, impressed by Bright's description of multiple petechial points of bleeding, considered concussion a diffuse contusion of the cerebral mass, that is the result of multiple minute injuries to brain tissue. The clinical changes following concussion also depend upon physiological alterations, such as disorders of the secretion of spinal fluid, changes in tonicity of intracranial blood vessels, alteration in meningeal permeability, etc. We must, therefore, change our attitude toward the term concussion and cease clinging to a conception formulated long before our present knowl-

edge of the anatomical and physiological changes following head injuries. We must give up the almost universal assumption that concussion implies no anatomical changes. We believe that some of the described changes persist in those patients who survive head injuries and that these account to a large extent for the clinical picture.

In spite of the probable difference in pathogenesis in the individual instance, these patients present a somewhat uniform clinical picture. The brain is known to react to various lesions and noxious stimuli in a very similar manner. They complain of headaches, dizziness, ready fatigability, intolerance to intoxicants, irritability, and difficulty in thinking. This symptom complex suggests an organic syndrome. It is not infrequently seen in early cerebral arteriosclerosis. On close clinical scrutiny the resemblance to a neurosis appears to be only superficial. Such similarity emphasizes the urgency of a careful clinical study of these cases. We feel that a more frequent utilization of what Strauss and the Author call the cooperative technic will facilitate such differentiation.

The headache in these cases is most often paroxysmal. It is usually described as a real ache or pain, rather than the "tightness and pressure sensation" reported by psychoneurotics. These pains in the head most often follow mental and physical effort. One must be very cautious in the interpretation of what many patients call dizziness. True vertigo is quite rare and a variety of abnormal experiences are reported to the physicians as dizziness.

The reiterated objection that each one of these complaints is encountered in the neuroses is no proof of the state of affairs in the particular case. Today one knows how closely psychogenic patterns of response may resemble organic disease pictures. The final opinion must depend on the impression that the whole clinical constellation makes on the experienced examiner.

It has been suggested that these cases be subjected to a series of studies which include a variety of technics available for the study of the intracranial processes. The presence of a few psychogenic features in a particular case does not rule out the existence of significant organic changes upon which the psychological reaction is

superimposed. This investigation should include:

1. Thorough neurologic examination.
2. Psychological and psychiatric study.
3. Otoneurologic investigation.
4. Spinal fluid studies including encephalography.
5. Other studies, especially of vegetative functions.

Bruns states that every case with the subjective syndrome due to organic intracranial injury will show focal signs if studied carefully enough. While our experience does not entirely coincide with that of Bruns,¹² it does seem that very careful neurologic examinations result in fewer and fewer negative cases as far as focal changes are concerned. Further refinements in our localizing technic will probably show us that our negative findings are often the results of cursory and inadequate examinations. It has been pointed out many times that the small traumatic lesions of brain tissue often give rise to what has been called "micro-symptoms"—slight changes that need very careful clinical survey for detection. Fragments of striopallidal disease are often missed. Bruns has pointed out the frequency in these cases and the significance of frontal ataxia, reflex changes, visual field disturbances, and mild cortical sensory defects.

The finding of a focal sign is merely confirmatory of the existence of organic disease. The injured adult who comes to us for examination has already been exposed to a variety of environmental stresses and disease processes with resulting modification of the soma. A mild hyperreflexia or a pupillary irregularity may be the result of disease antedating the trauma. The positive findings must be evaluated in the whole clinical setting, including the past history of the patient. All these methods must be applied cautiously and wisely. The proper evaluation of the results of all these examinations will always depend on the clinical judgment and acumen of the attending neuropsychiatrist.

We are all groping for more reliable methods of objectifying the intracranial damage resulting from head injury. During the long history of this subject many methods were suggested though soon rejected by clinicians. The methods which we have discussed are worthy of further trial. Some of the technics have already

been found unreliable. We have not been able to confirm the value of the KI method used to study the resorption of the cerebrospinal fluid. We are still uncertain about the value of the Muck test. The Baillart method of measuring the pressure in the retinal artery has given us very interesting and promising results. It is worthy of further trial.

Encephalography has proved to be an invaluable aid in our investigations. It sometimes reveals striking evidence of the existence of intracranial damage. The existence of sources of error in a clinical procedure does not entirely invalidate its application. These pitfalls and limitations should be recorded and impressed upon those who are using the method. It is obvious that preexisting defects of the ventricles should be ruled out by looking for all other possible causes for such distortions in the past history of the patient. Slight dilatations of the ventricles may be the upper limits of the normal range of variation in size of the ventricle.

The objections of Kehrer, Reichardt, Hall and Mackay and others that we do not know enough about the normal controls in encephalography are being answered by the remarkable accumulation of encephalographic experiences in the last decade. Bielschowsky studied 100 controls. The author would like to caution the interpretation of encephalograms in older patients who may have extensive arteriosclerosis of the smaller cerebral vessels and who may show marked cerebral atrophy and a hydrocephalus ex vacuo. One must accept the value of definite hydrocephalus internus with rounded out ventricular horns, of the unilaterally enlarged ventricle with an occasional pulling of the ventricle toward the side of the lesion, unusually extensive accumulations of air over the cortex. A normal encephalogram does not rule out the existence of an organic post traumatic affection. We have made the diagnosis of organic disease with a normal encephalogram. The aerogram is only one of the methods at our disposal. The critics of this type of approach to the subject of head injury have overemphasized the significance we attach to the encephalogram.

Further studies have confirmed the fact that occasionally the postconcussion syndrome is due to increased spinal pressure. Two such cases were seen in the last year at the Morrissania Hospital. One was a

child of 8 with persistent headache and dizziness, following a head injury of moderate severity a few weeks before admission. There were no other signs of intracranial damage. The symptoms were completely relieved by a spinal tap. The other case was a man of 32 who sustained a severe head injury five years before. Except for some suppression of associated movements on the right when walking and a hyperactive left knee jerk with slight posturing of his head toward the right there were no focal signs. A lumbar puncture showed increased pressure with striking relief after the removal of a small amount of spinal fluid. The Ayala indices in these cases were high, showing that there probably existed an increased accumulation of cerebrospinal fluid. This condition may progress to the point where bilateral papilledema may appear and more drastic measures for relief of pressure may be necessary. In our experience even such cases responded to simple lumbar drainage. In a previous communication Strauss and the author¹ have shown that occasionally a very low spinal pressure is found. In these cases air insufflation by the lumbar route has proved of great therapeutic value, probably due to the breaking up of meningeal adhesions by this procedure.

There can hardly be any doubt about the fact that the increased spinal pressure in these cases accounts for the symptoms. The relief by puncture is definite. Some of the patients have returned requesting relief by lumbar puncture. The contention of Kehrer¹⁵ that increased spinal pressure may be psychogenic can hardly be viewed seriously. This writer offers no clinical data to substantiate this bold statement.

Not infrequently the most incapacitating symptom is an inability to think, to do any relatively complicated intellectual work. In certain types of workers, such as physicians, teachers, etc., such defects may be even more significant than a mild weakness of a limb. During the war a number of investigators, like Pfeiffer,¹⁶ attempted to evaluate and measure the extent of such impairment of the intellect. It must be noted that decreased capacity for intellectual performance may be the result of undue affective lability or a defect in volition. The further investigation of the nature of these alterations in conscious psychologic processes merits the attention of clinicians.

The results of Oberholzer²⁰ with the Rorschach test, of Storrington²¹ with ergogra-

phic curves, and of De Santis²² with memory tests, are instructive and merit the closer attention of neuropsychiatrists. The clinical applicability of these procedures is as yet doubtful. Definite and practical suggestions are as yet not available. Mrs. Conkey is studying this problem at the present time at the Morrisania Hospital.

It must be borne in mind that the defect is often limited to the most complex intellectual processes so that simple clinical tests may fail to reveal any abnormality. Most psychological tests do not duplicate the exigencies of life. In spite of excellent performance on a battery of mental tests, school progress and efficiency at work may remain persistently bad. The conditions of the psychological laboratory are necessarily artificial. There is lacking the natural clash with hostile environmental forces. Recently the author examined a girl of 16 who did very poorly in her high school work following a head injury in an automobile accident. Thorough psychological examination showed nothing abnormal. She admitted that her attitude was different in the classroom. She found it impossible to recite and during the stress of an examination could not recall simple facts of importance at the time. No such difficulties had been experienced up to the time of the accident. In this case, while the elementary psychological processes seemed intact, a defect in psychic integration existed, perhaps in the proper mobilization and synthesis of psychic energy. There still exists considerable difficulty in measuring such a defect, though the literature in experimental psychology contains some very valuable suggestions.

An intensive clinical study is urged in all unclear cases. It is unnecessary to spend the time and energy for cases with obvious defects and focal signs. Special investigation should be undertaken of the most important complaints. In cases with visual disturbances everything should be done to study the cause of the complaints. The presence of psychogenic complications should not make it unnecessary to study the case carefully. These methods are attempts at arriving at the truth. Some are more reliable than others. They should be used with the same precautions as other instruments of investigation. Formulae, quotients, and coefficients of correlation will never replace the opinion of the experienced clinician.

Much of the literature on the sequelae of trauma is the result of the experience of men who see many industrial accidents. It is evident that in that type of material the desire for adequate compensation looms large in the clinical picture. Almost all the cases are complicated by the possibility of secondary gain from illness. The postconcussion syndrome, therefore, is not as often seen as clearly as in the practices of those physicians who see cases where there exists no compensation or insurance problem.

Many objections have been voiced against the acceptance of the postconcussion syndrome as a clinical entity. There are a number of reasons for this widespread reluctance to admit the organic nature of the postconcussion syndrome. These reasons are:

(1) The assumption that an organic syndrome is more serious and therefore more compensable than the psychogenic reactions. This generalization is not true. Some of the most incapacitating and devastating reactions to head trauma are seen in purely functional reactions. Recently the author saw a man practically confined to his bed and helpless for six years, with an undoubted, severe functional response to the trauma situation. The author has never seen a case so disabled by an organic lesion. Frequently the very severe organic lesions end in death. The survivors usually show a progressive tendency to recovery and to restoration of the intracranial equilibrium. Our observations confirm the impression that there is a progressive tendency to recovery if secondary psychological elaborations do not set in. The possibility of restoration of function, even with the removal of extensive areas of the brain, has been demonstrated many times. Cooper,²³ almost a century ago, showed that extensive destruction of the brain can take place without significant functional impairment.

(2) The tendency in certain parts of the world to deny compensation for the functional cases. This has been especially true in Germany. Such an attitude has called forth a rather vigorous attack on the organic nature of the postconcussion syndrome. The acceptance of the psychogenic nature of this symptom complex by legal authorities will exclude a very large number of cases from receiving any compensation. The financial implications of such a decision and this point of view are obvious. The experts for the insurance companies

have therefore redoubled their efforts to disprove the organicity of the syndrome. They have once again emphasized the pathogenetic significance of the desire for compensation. We have insisted that in many cases of head injuries the psychological elaborations are merely secondary complications and at times more important and incapacitating than the original organic injury.

(3) That there are no objective criteria and that simulation will therefore be encouraged. One of the first reactions of a prominent neuropsychiatrist to the presentation of our point of view was the fact that it would encourage the number of fraudulent claims. Very careful clinical study will detect the simulator. In almost all the cases we studied we found objective evidence of intracranial injury. In those cases who do not present such objective criteria the differentiation is more difficult but can usually be made on clinical grounds. One might as well argue that there is no such thing as early paranoid dementia praecox because it is easily simulated and there are no objective criteria for diagnosis. It would exceed the limits of this paper to discuss the interesting problem of the detection of the simulator.

In this attitude of some experts one traces the influence of legal procedure on medical practice. The courtroom demand for objective evidence cannot always be met by physicians. Much of our medical opinion is based on reports of subjective experiences by patients. The question whether the patient is honest or simulating usually depends on the total impression that the behavior of the patient makes on the physician.

(4) That there is no definite organic basis for the disease. Kehrer maintains that a disease entity cannot be created without a definite morphologic substratum. Such a time worn conception of the nature of disease cannot be upheld at a time when migraine, epilepsy, Raynaud's disease, myasthenia gravis, and narcolepsy are fairly well established. While no constant anatomical changes have been established, it is probable that the petechial hemorrhages, changes in the meninges, alterations in glial activity and other described brain changes play an important part in accounting for the clinical changes. There exists in addition a great deal of evidence that physiological changes within the

cranium are responsible for the morbid manifestations.

(5) That premorbid instability and other constitutional defects are frequent in those who most often show this subjective symptom complex. This fact is said to prove that the symptoms are only psychologic responses to the trauma in predisposed individuals. Nervous and mental diseases were not more frequent in our patients than in others suffering from varied medical and surgical complaints. The existence of constitutional defects and predispositions has no bearing on the question of the organicity of a given disease process. The morbid phenotype is always the resultant of the interaction of genetic and environmental factors. It is well known that the reaction to physical stresses, even to bacterial invasion differs. A significant constitutional factor has been demonstrated in rheumatic fever (Draper), pneumonia (Pearl), and chronic encephalitis (Löffler). Constitutional factors may also determine the particular form which a disease process will take. Such modifying influences on the nature of morbid reactions have been described by Fleck in chronic encephalitis and Schneider in general paresis. It is known that an unstable individual, a psychopath will more readily become delirious in reaction to an infection (Birnbauum). It is therefore not surprising if the unstable and constitutionally handicapped respond more seriously to head injury and more readily develop psychogenic complications.

The whole problem needs a great deal more study. We must all endeavor to divest ourselves of prejudices for and against the injured. The legal considerations should not confuse the medical expert. Wishful thinking should be avoided and something should be done to resolve the scotomata of many of our medical colleagues when they approach a traumatic problem. The organic factor in head injury merits further attention.

1814 GRAND CONCOURSE DISCUSSION

DR. EUGENE N. BOUDREAU: Relating to the anatomic and physiological approach to the discussion, I am surprised that Dr. Savitsky does not refer to the complete piece of work published by Adolf Meyer in 1903. That undoubtedly represents the full appreciation of the subject at that time. What fundamental contributions have been added since that day? There have been contributions on the spinal fluid which, however, have not changed materially our con-

cepts or given us better channels of therapy. Of course, Temple Fay and others have stirred us to pay greater attention to this angle of approach. The establishment of new facts relative to the vessels of the brain—I am referring to the vasomotor control and the demonstration of collateral circulation—have very material relevancy. These new facts certainly tend to change our viewpoints about the physiology of brain trauma. But as yet have we arrived at the point where our various attacks by neurological examination, spinal fluid pressure readings, encephalography, etc., give us definite and conclusive results when interpreted? There still is a wide realm of uncertainty. This is so because of the intricacy of the mechanisms involved. Dr. Savitsky indicates that his experience has been conclusive in some cases.

I think, as Meyer showed by his reports, that as a result of the unevenness of the cranial floor, the sharp margins of the tentorium and the varying density of the brain substance, even slight external violence is likely to cause some physical injury to the brain tissue. This he found frequently at the various poles and about the ventricles. As yet, it seems to me impossible to demonstrate the absence of such injury in any case even with the careful approach described by Dr. Savitsky.

I have a feeling, therefore, that aside from the few cases of encephalography where evidence is definite, the other procedures cannot be depended upon.

I agree with Dr. Savitsky that long clinical experience is still most necessary in differentiating the organic from the nonorganic reactions.

So far as the latter are concerned it is my experience that the attitude and care given the injured person in the first instance is most important. The shock injury and the later necessity of the individual to defend his honesty, honor, and self-respect precipitates a psychic reaction that requires long effort to change or correct.

The point made that the injury may release psychic phenomena is, of course, well taken. But a brief discussion cannot do adequate justice to this splendid effort of Drs. Strauss and Savitsky. However, I am glad of the opportunity to express my appreciation of their industry in clarifying the subject further by these exhaustive researches.

ACCIDENTAL DEATH

He had a prophylactic bent
And led a sterile life,
Had hygienic children and
A sanitary wife,
Lived in a fumigated house
And wore aseptic suits,
Ate germicidal food and smoked
Denicotined cheroots.

His milk was always pasteurized,
He drank denatured water,
He ne'er forgot to swat the flies,
Mosquitos he would slaughter.
He screened his doors and windows,

His office disinfected:
Against microbes of every kind
He felt himself protected.

He exercised, he slept by rule
And timed his every breath,
His health was excellent and he
Defied disease and death.
His plan was admirable, no doubt,
Alas, the measly luck!
He went out and got run over
By a ten-ton power truck.

VICTOR LEVINE,
in the *Nebraska State Medical Journal*.

SERUM SICKNESS A CLINICAL AND EXPERIMENTAL STUDY*

Preliminary Report

JAMES R WILSON, M.D., T C WYATT M.D. JAMES BENNETT, M.D.
O D CHAPMAN, M.D. AND C KNOWLTON M.D.

From the Departments of Pediatrics and of Bacteriology, Hygiene and Preventive Medicine of Syracuse University College of Medicine

Our remarks will be confined largely to a phase of the problem of serum sickness which has to do with certain nonspecific inhibitory factors. Our work began with observations on the effect of fasting and ketogenic diets in asthma. Then there was a study of serum sickness and later, observations on the effect of fasting on anaphylactic shock in guinea pigs. All of this work was related—we were interested in a phase of the problem of nonspecific inhibition of certain allergic phenomena. The following is the story of our work briefly summarized.

In 1930 one of us encountered a difficult subject to deal with—a child with asthma. Many of the things that provoked attacks were removed from his environment and from his diet, but it was impossible to remove all of them and he reacted unfavorably to adrenalin and ephedrine. A report of Peshkin and Fineman had very recently appeared in the *American Journal of Diseases of Children*, relating their experience with ketogenic diets in asthma. The case was studied from that standpoint. The results were encouraging and suggested further study.

The nonspecific effect of a mild to moderate degree of ketosis was studied in other subjects. Some of them were benefited. In one instance it was possible to completely inhibit attacks in the presence of the same given cause. In this particular subject it is still possible to do this with ease. In other instances we appear to have altered attacks of asthma by means of fasting, low carbohydrate submaintenance diets or fat rich diets, sometimes supplemented with such drugs as hydrochloric acid by mouth or ammonium chloride in large doses. At times the treatment was reported as more disagreeable than the asthma but we did not mind that, particularly if our observations told us something about nonspecific inhibitory effects.

Because of the many factors involved and because of the scarcity of asthma in the hospital wards we decided to go elsewhere for material. At the time, serum sickness was being frequently observed at

the Syracuse City Hospital for Communicable Disease and in the case of that particular condition there are fewer complicating factors than in asthma. The majority of subjects receiving therapeutic horse serum were sufferers from scarlet fever. Most of these subjects were not frightfully ill. The incidence of serum sickness was high. Through the courtesy of Dr. Silverman it was possible to observe all persons receiving therapeutic horse serum and to follow each for approximately one month under controlled conditions. This was an almost ideal set up. Our methods and the results of our observations are briefly as follows.

Control subjects were given an anti-ketogenic diet, care being taken to give them enough carbohydrate to prevent the appearance of acetone in the urine. Treated subjects, immediately after receiving serum, were placed on a submaintenance low carbohydrate diet in order to induce a ketosis if one were not already present. A mild to moderate degree of ketosis was maintained for a period of two weeks. Urine specimens were examined three times a day shortly before mealtime. During the first winter we gave hydrochloric acid to treated subjects with each meal. Subsequently HCl was discontinued and the results of ketogenic diets alone observed. The results were not quite as good when we omitted HCl from the diet but we are not at all certain of the significance of this finding.

Our correlated studies are based on observations made on 55 especially treated subjects and on 97 control subjects. Signs of serum sickness were observed in 78, or 80 per cent of the control subjects and in 26 or 47 per cent, of the persons maintained in a state of ketosis (hereafter called the treated group). Generalized urticaria occurred in 73, or 75 per cent, of control subjects and in 21, or 38 per cent, of the treated subjects. Joint pain was recorded in 40, or 41 per cent, of the controls and in 15, or 27 per cent, of the treated subjects. (In this connection an urticarial reaction beyond the site of the area where the serum had been injected

* Aided by a grant from the Heidricks Fund

was considered as a generalized reaction, even though very few hives were seen in some instances. Also, we may have been fooled in certain instances of joint pain, but in general we think that our observations were quite accurate.)

These observations suggest that the incidence of serum sickness was reduced as a result of the special treatment used. Other data suggest that, in addition to a reduction in incidence, the duration and the degree of discomfort were also altered. For example, when the average duration of generalized urticaria was calculated for individuals actually suffering from that condition, it was found that the average for the treated group was 35.2 hours and for the control group, 57.1 hours, the difference being 21.9 hours. (The average duration of joint pain showed no appreciable difference in the two groups.) The data just cited do not take into consideration the reduced incidence of serum sickness in the treated group. Calculated with that in mind, more striking difference can be demonstrated in both cases.

The degree of discomfort due to serum sickness was estimated in all subjects suffering from that condition. The results, of necessity, are only approximate. However, the same criteria were used for both control and treated subjects. Tabulated data suggest that there was distinctly less discomfort among the treated subjects.

But in spite of the fact that the data thus far presented appeared to show that a mild to moderate degree of ketosis tends to inhibit the clinical evidence of serum sickness, it is possible that the size of the series is too small to warrant any definite conclusion. In view of this fact it was felt that if it could be shown that the reduced incidence appeared in one group of the treated subjects and not in another, we might have more convincing evidence to present. Thus it came about that, in correlating results in different ways, we could divide our treated subjects into two groups, one of which showed a marked reduction in the incidence of serum sickness and the other did not. This was not true of control subjects. For example, treated subjects who had exhibited positive skin sensitivity tests to horse serum (before the injection of therapeutic horse serum) suffered from serum sickness just as frequently as did the corresponding control group. On the other hand, treated subjects who had exhibited negative skin

sensitivity tests to horse serum exhibited a markedly reduced incidence of serum sickness. Table I illustrates this better than it can be described.

TABLE I

Treated series	Number of subjects.....	Skin sensitivity tests	
		Positive	Negative
	Incidence of serum sickness	16 14 (88%)	31 8 (26%)
Control series	Number of subjects.....	Skin sensitivity tests	
		Positive	Negative
	Incidence of serum sickness	18 17 (94%)	38 27 (71%)

The fact that serum sickness was reduced in treated persons with negative skin tests and not in treated persons with positive skin tests, seems to be one of the most interesting bits of data that we have collected. It tends to suggest that the threshold mechanism was affected in one group and not in the other, perhaps because our nonspecific method was not sufficiently potent to affect the more sensitive individuals.

STUDIES ON THE EFFECT OF FASTING ON ANAPHYLACTIC SHOCK IN GUINEA-PIGS.—During the course of our observations at the City Hospital it became apparent that animal studies might shed some additional light on the subject. As a result of discussions with Dr. O. D. Chapman, Dr. H. G. Weiskotten, Dr. Wm. Groat, and others, preliminary tests were made. Dr. Chapman has been actively interested in this work and has made it possible for us to use his laboratory and animal room.

Our first experiments were designed to answer the question: *What is the effect of fasting on anaphylactic shock in guinea-pigs?* Twenty young pigs were used in each experiment—ten fasted and ten controls. The ten fasted pigs were deprived of food and water for three days before the shocking dose of serum was given. The ten control pigs were fed their usual ration up until the end. The first experiment was terminated at eighteen days (after sensitization), at which time a shocking dose of serum was given and the clinical effects observed. Both in this experiment and the next one which was terminated on the twentieth day, we were unable to detect any difference between the manner in which control and fasted pigs reacted to the second or intoxicating dose of serum.

These two experiments seemed at first to tell us that fasting in the manner described did not influence the clinical evi-

dence of anaphylaxis. We were at first discouraged and the animal work was temporarily abandoned.

Next came our observation that a mild to moderate degree of ketosis appeared to influence the course of serum sickness in "less sensitive" subjects (on the basis of skin sensitivity tests) and did not appear to do so in the "more sensitive" subjects with positive skin sensitivity tests (see Table I).

Since it has long been known that guinea-pigs gradually develop a sensitivity after having been given a preliminary or sensitizing dose of horse serum, it was decided that we observe the effect of fasting before the peak of sensitivity had been reached. Our next experiments were designed to answer the question—*What is the effect of fasting on anaphylactic shock during the period of developing sensitivity?*

With the particular technic and dosages of serum adopted we found that the peak of the sensitivity curve was reached at about sixteen days after the sensitizing dose of serum had been given. Experiments which were conducted as were our first two, but which were terminated during the period of developing sensitivity gave us the following data:

Among the control animals little evidence of sensitivity (as manifested by signs of anaphylaxis appearing after the intoxicating dose), was observed at eight days, slightly more at ten days, more at twelve days, and so on up to and including sixteen days.

Fasting (no food and no water) for a three-day period before the shocking dose of serum was given constituted the special treatment of the various treated groups. Among the fasted groups of pigs little evidence of sensitivity was noted at eight days, little at ten days (evidenced as stated before, by signs of anaphylaxis appearing after the intoxicating dose of serum had been given), little at twelve days, slightly more at fourteen days and slightly more at sixteen days. The curve of developing sensitivity appears to rise at different rates for fasted and nonfasted pigs. Fasting appeared to exert a protective effect in these experiments, up to and including the

sixteenth day. Our most striking results came in one of the sixteen-day experiments in which six of the control pigs died and another nearly died but recovered. None of the fasted pigs died and only one of the ten suffered from a severe reaction.

Since eight experiments, in which a total of 160 pigs were used, exhibited evidence of the inhibitory effect of fasting during the period of developing sensitivity, we felt justified in proceeding to the next question: *What is the effect of fasting on anaphylactic shock after the peak of sensitivity has been reached?*

Using the same technic and the same dosages of serum that we had used in previous experiments, we proceeded. This time experiments were terminated at eighteen and at twenty days after sensitization. Control experiments appeared to show that the peak of sensitivity was reached at sixteen days and that there was a very slight falling off on the eighteenth and twentieth days. Whether or not this is an absolutely true statement cannot be said, but it does appear to be true that (with the technic described) eighteen and twenty days represent points very close to the peak of the sensitivity curve. Six experiments were conducted. Twenty pigs were used in each. In all six of these experiments we were unable to detect any difference in the manner in which control and fasted pigs reacted to the second or intoxicating dose of serum. In these experiments fasting failed to exert an inhibitory effect on anaphylactic shock.

The fact that fasting appeared to exert an inhibitory effect during the period of developing sensitivity and failed to do so when the peak was reached or slightly passed, was of particular interest to us in view of our findings in serum sickness. In serum sickness we observed different effects in the "more" and the "less sensitive" subjects, and in our guinea-pigs we observed different effects during the period of developing sensitivity and afterward.

In presenting this work we wish merely to report the results of our studies. The implications will be left to the reader to cogitate.

PHYSICAL THERAPY IN GENERAL PRACTICE

HAROLD J. HARRIS, M.D.
Westport, N. Y.

This topic is a large one since to the general practitioner comes almost every condition and his work includes parts at least of most of the specialties. The extent to which the general practitioner uses physical therapy in the varied array of diseases, syndromes, and injuries, depends largely upon his familiarity with physical therapy and the extent of his equipment. His idea of the value of physical therapy varies directly with the amount of experience he has had with it or with his opportunity to observe the results obtained by others.

EQUIPMENT

The following equipment has proved to be very valuable in general practice, but not all of it is essential. (1) A heavy duty, high voltage, high frequency machine delivering the usual currents. (2) A portable high frequency machine for light work in the office or treatment of bed-ridden patients. (3) A cutting current machine, separate rather than incorporated in the high frequency apparatus, for convenience as well as portability. (4) A generator of galvanic current. (5) An ultra-violet generator, combining air- and water-cooled burners. (6) A whirl-pool bath. (7) Heat lamps, both infra-red and luminous ray. (8) An x-ray machine for superficial therapy. (9) A portable sun lamp using the S-1 incandescent bulb.

The cutting current has been found most useful as a separate unit. Obviously, however, adequate training with this current as well as surgical experience are essential before it may be used with propriety and safety, if it is used at all.

The galvanic current is still found almost as useful as it was several years ago although diathermy, medical and surgical, has supplanted it in many conditions. Many things can be accomplished by no other modality. The author has had no experience with the static generator although its value is well proven.

Many types of ultra-violet generators are available. The water-cooled lamp is apt to be of as much value as the air-cooled.

"Heat lamps" are indispensable com-

ponents of equipment, the luminous ray for some conditions and the infra-red lamp for others, while for still other conditions they may be used interchangeably.

CONDITIONS TREATED

Only those conditions frequently encountered in general practice in which physical therapy is preëminently valuable will be discussed. There are, of course, innumerable conditions in which physical therapy *may* be used to some advantage, but there are also many conditions which yield to nothing else so quickly and so well as to one or more physical therapeutic procedures.

INFECTIONS AND INFLAMMATORY CONDITIONS.—*Pneumonia* has headed the list, not just because of the dramatic effect produced upon it by diathermy but because it is the most serious of the acute conditions one treats with physical therapy. The relief of pleuritic pain is striking. Dyspnea has improved and cyanosis has markedly lessened in all cases treated. The author believes that the course of the disease has been shortened and an occasional death prevented by the beneficent effect of heat and resultant improved circulation through the consolidated lung tissue. It has been especially apparent that lobar pneumonia, treated from its onset by diathermy, ends by lysis, thus sparing the overtaxed heart the added shock of crisis. The treatments should be fairly long, unless the patient tires from it, and they should be given at least twice daily.

Unresolved pneumonia which occurred in a surprisingly large number of cases several years ago—some of which had been treated with diathermy and some without—yielded so nicely to diathermy that one cannot doubt its effect after using it. There seems reason to believe that routine radiographs following all pneumonias may reveal some otherwise unsuspected cases of failure of resolution which can easily be cured. If undiagnosed, some of these cases may result in recurrent pneumonias—a reinfection of the old focus—perhaps a year or more later.¹

Diathermy is also of value in bronchopneumonia and acute bronchitis. Chronic

bronchitis and bronchiectasis receive at least symptomatic improvement.

There seems no more common condition properly treated by physical therapy than *acute and chronic frontal and maxillary sinusitis*. The vast majority of sinus infections not only are relieved by radiant heat, but they get well under treatment. In more than 10 years the author has not referred a single patient with acute or chronic sinusitis for washing of the antra, suction, turbinate or septum resection, nor radical operation, because of the good results from luminous heat, ultra-violet ray locally, and occasionally with the addition of diathermy.

Much can be accomplished in the treatment of *chronic arthritis*, but only in a limited proportion of cases. Kovács² states that the most important forms of physical therapy in chronic arthritis are heat, general and local, from radiant or high frequency sources or through the medium of water, heliotherapy—natural and artificial—the galvanic and static currents, massage and exercise. The author has had some very gratifying results from diathermy as the only physical method of treatment, especially in the single joint involvement or in the bilateral knee joint, arthritis of the middle-aged. It is, of course, obvious that physical therapy alone does not comprise good clinical management of the arthritic.

Neuritis occurring with arthritis or alone yields to the same measures in a much higher percentage of cases, especially if the basic condition, as focal infection, is removed. Diathermy has been the most useful agent and, with persistence and proper application and long treatments, seldom fails to cure. The neuritis accompanying *subdeltoid bursitis* has been the commonest as well as the most crippling and painful type treated. Heat cures the neuritis by causing absorption of the calcareous deposit in the bursa responsible for it. Radiographs "before and after" tell the same story of relief that the patient so happily reports.

Herpes zoster either in its neuritic stage or after the appearance of the vesicles, is markedly influenced by ultra-violet light. If the diagnosis can be made before the eruption appears, it can actually be prevented, the pain relieved and the disease aborted. In the eruptive stage, pain is relieved and the vesicles dry quickly.

Chronic cholecystitis need not always be

a surgical condition. In several cases the author has observed a gallbladder function markedly impaired on x-ray examination, and on repeating this x-ray procedure after a course of treatment, found a normally functioning gallbladder in the symptom-free patient. The treatment must be long—at least forty-five minutes of full heat—and must be given almost daily until subjective improvement is experienced and then tapered off to three or two times weekly. Occasionally a second course of treatment is necessary within a few months or a year.

Tuberculosis of the larynx, in an advanced stage, complicating advanced pulmonary tuberculosis was so promptly cured in one patient, as to seem a life-saving measure. Tuberculosis of the bones, joints, and peri-articular tissues will often receive such excellent effect from heliotherapy, natural or artificial, that institutional care can be dispensed with. General and local treatment with ultra-violet light has resulted in several cures in such conditions. Intestinal tuberculosis, with the ray applied over the abdomen only, does very well under long and repeated courses of treatment.

Tonsillitis, whether caused by a streptococcus or the organism of Vincent's angina, usually resolves within a day or two after thoroughly raying of the tonsils with the Kromayer lamp, using a quartz rod. In the stage just preceding suppuration in developing peritonsillar abscess either the process is aborted or suppuration hastened by the use of a similar technic.

Pharyngitis, in the acute stage yields readily to exposure to ultra-violet rays. In chronic pharyngitis the author has had less success.

TRAUMATIC CONDITIONS.—*Low back pain*, whether due to sacro-iliac or lumbosacral strain, yields steadily though at times somewhat slowly to diathermy. With a small block tin electrode over the site of strain and a larger one over the abdomen, treatments lasting forty-five minutes are given daily until marked improvement occurs; thereafter they are given three times weekly. The patient almost always receives definite relief from the first treatment and usually not more than ten are required.

For the *sciatica* so commonly accompanying these strains, it is usually advisable to treat through the upper thigh with one electrode over the lumbosacral r

and the other either encircling the thigh or applied to its anterior surface above the knee. In some cases application through the pelvis, with the smaller electrode over the sacrum covering the nerve roots, is of more benefit.

In *sprained ankles*, knees and other commonly encountered sprains, diathermy logically helps nature's efforts to absorb exudate and to heal torn ligaments. By increasing the blood supply it shortens disability demonstrably. Usually heat from an infra-red or luminous heat lamp is used before the diathermy, or even radiant light alone is of real value.

The whirlpool bath has given much comfort and probably actually promotes healing through increased circulation, in *fractures of the extremities* where the cast or splint can be removed and the part immersed.

In the severe *contusions* that occur so often in industrial injuries, whether it be only a black eye or a deep-seated hematoma in the gluteal region, heat as from an infra-red generator, helps visibly in promoting absorption and relief of soreness, dysfunction and pain.

In the aftercare of fractures the effect of heat, converseive and convective, is well known. Many a well-reduced Colles or Potts fracture heals perfectly but with so much soft tissue damage resulting in fibrosis as to seriously impair the usefulness of the part. In these cases early active motion, radiant heat, and diathermy have revolutionized the former long immobilization and, trust-to-nature technic.

Lacerations, especially the ragged potentially infected ones, quite naturally heal more quickly and with fewer serious infections under the beneficent rays of the ultra-violet lamp and the luminous heat bulb.

It is probably in *burns*, of all degrees and of any extent, that the effect of the luminous ray is best demonstrated. The lamp is, for obvious reasons, kept at a comfortable distance from the burned area, vesicles are not broken, and the patient is not only made comfortable more quickly than by any other method the author has used, but healing is promoted with almost amazing rapidity.

The very fact that all large industrial enterprises maintain their own physical therapy departments, even under the eye of their efficiency experts, is proof of the economic value to the concern.

SKIN CONDITIONS.—*Impetigo* is one of the commonest skin diseases seen in general practice. Its response to the time-honored and usually efficient local applications is often disappointing. It responds uniformly well, however, to repeated doses of ultra-violet light, using either the air-cooled or the water-cooled lamp. A dosage just under the blistering one seems necessary.

Of the serious skin infections that yield to physical therapy *erysipelas*³ is a shining example. It yields readily to ultra-violet light, from either type of lamp, obviously because of the direct bactericidal effect of the ray. It seems far preferable to use this simple, harmless method in the ambulant patient than to risk sensitization, serum sickness, or anaphylaxis from the use of antistreptococcus serum, except in those patients who are brought to us when already extremely ill.

Other superficial infections yield as readily to ultra-violet light as does erysipelas. Ultra-violet light will control any infection that it can reach. Its efficiency, however, is limited by its depth of penetration and the difficulty in raying the entire infected surface of the skin and mucous membrane.

Pityriasis rosea, will clear up within three or four days after ultra-violet light, if a second degree erythema over the whole affected skin area is obtained.

Ringworm of the feet and body, *furuncles*, *boils*, some forms of *eczema* and *acne vulgaris* all yield to ultra-violet light but, when available, the roentgen ray is preferable. Carbuncles and boils will either be aborted promptly, if seen early enough, or will suppurate and drain quickly if treated later.

A combination of luminous heat and the air-cooled quartz light often bring about early healing of *indolent ulcers*, that yield to nothing else.

Alopecia areata usually disappears after a fairly prolonged course of ultra-violet light. In premature baldness or thinning of the hair the author has found that ultra-violet light will at least temporarily arrest its steady march if given frequently and to an intense erythema.

GYNECOLOGICAL AND GENITO-URINARY CONDITIONS.—Gynecological cases come in great numbers to the general practitioner, especially to the rural one. In some of these patients we can, by physical therapy procedures, accomplish so much that it is to be deplored that there is not more wide-

spread knowledge concerning their treatment by these means.

Endocervicitis is probably the commonest condition in this group. It is of real importance to the patient from the standpoint of comfort and may actually be of major importance as a focus of infection or as a site for the development of cancer. The technic and method of treatment may be varied. The author has had some excellent results in the most hopeless looking crevices from the use of galvanic current, using a copper intracervical electrode or Tovey copper electrode. More recently he has employed the cherry diathermy electrode with quicker effect.

Gonorrheal salpingitis furnishes us with the best reason for emphasizing physical therapy in gynecological conditions. The acute stage can be greatly shortened by the use of a vaginal electrode of the pattern of the Chapman electrode and a wide block-tin belt electrode. The very small diathermy units will not deliver enough current to give adequate heat for this technic. Treatments must be prolonged and frequent at first. In nearly every case there is relief from pain following the first treatment. Tenderness, rigidity, and the pelvic mass usually have disappeared within a week or two. If pain is aggravated by the treatment, it should be discontinued, at least for the time being.

If the patient is seen in the chronic stage, much can be accomplished in promoting resolution of the pelvic mass, to the point of complete restoration in some cases, with consequent preservation of important structures. Operation, with the sacrifice of uterus, tubes, and ovaries, can thus often be avoided.

For the persistent gonorrheal infection of the cervix, if the usual medical treatment has failed to bring about a disappearance of gonococci and discharge, the author has found that two to four treatments with the intracervical electrode of Corbus⁴ using a belt electrode, will bring about a cure in a large percentage of cases.

The same electrode may be used for the female urethra in gonorrheal urethritis, but a temperature not exceeding 113° F. is attained. Corbus and O'Connor state that in the average case the gonococcus cannot be found in the urethral strippings after one or two treatments.

Urethral caruncles are best destroyed by the Oudin current or by coagulation, as

are venereal warts or ordinary warts anywhere.

The pain of ureteral stricture may be relieved or stopped by diathermy applied through the abdomen at the level of the lesion. Along with mechanical dilatation through a cystoscope it is of great help, apparently not only relaxing spasm but possibly also helping to cause absorption of scar tissue.⁴

Dysmenorrhea is usually relieved by diathermy, either through the vaginal and belt electrode combination or by anteroposterior application through the pelvis. It is best given during the few days preceding the period. No ill effects other than slightly increased flow are noticed, even if it is given at the time of menstruation.

In the dysuria of elderly men which is aggravated by the boggy swelling of the hypertrophied prostate in a fair proportion of cases, diathermy administered by means of a rectal electrode and a dispersive block-tin abdominal electrode, will give such grateful relief that it is well worth trying. The hypertrophy itself is not affected, of course. Probably the effect described is as much from relaxation of sphincter spasm as from decongestion of the gland.

The same technic is used with splendid results in gonorrheal prostatitis.

OTHER CONDITIONS—ELECTROSURGERY.—The cure of rickets is certainly hastened by general irradiations with ultra-violet light although natural sunlight plus the proper vitamins accomplish as much if not as quickly.

Circulatory conditions including angina pectoris, endarteritis obliterans, phlebitis, Raynaud's disease are benefited, to some degree at least, by the careful use of small doses of diathermy.

Many surgical procedures have become office methods with physical therapy. The electrocoagulation of selected cases of hemorrhoids is a noteworthy example. Unless the area involved is too extensive or the tissues too swollen, hemorrhoids may be coagulated under local anesthesia and the patient allowed to go home. In extensive involvement the postoperative disability may approach that of orthodox surgery. Rectal and anal polyps are coagulated or desiccated. Obviously these procedures are not to be undertaken without special training.

A popular but very questionable office

procedure is electrocoagulation of tonsils. It is applicable in the aged, in bleeders, or in otherwise poor surgical risks, in the hands of the adept operator.

The treatment of hypertension by high frequency is losing its popularity. The author has seen no lasting good come from it.

The destruction of skin growths by surgical diathermy or their excision with high frequency cutting current is properly a part of general practice, provided training, equipment, and technic are good. Warts, moles, and some birthmarks are best treated by fulguration or coagulation. A thorough knowledge of the pathology of these conditions is also essential if their removal is to be undertaken. The thoughtless desiccation or coagulation of a blue or black mole may result tragically in metastatic melanotic carcinoma and death.

SUMMARY AND CONCLUSIONS

Physical therapy procedures are adapt-

able to the treatment of almost innumerable conditions in the general practice of medicine, to the great benefit of the patient. A few of the most useful have been mentioned. Proper training, good equipment, and a rigid standard of ethics are essential in this as well as in all branches of medicine. Slipshod methods, inadequate diagnosis, too hasty treatments given by poorly trained physicians and technicians are, of course, to be condemned. No one now denies that physical therapy is filling a great need in general as well as specialized practice.

AUSTRALIA'S HOSPITAL LOTTERY RACKET

Those interested in the efforts to start lotteries here to finance relief may like to have a glimpse of how they work in Australia. The hospitals there, as here, have been swamped by a flood of charity patients, and at the same time have been their revenues shrink alarmingly. The Australian correspondent of the *A.M.A. Journal* reports that in Queensland since 1920 the government has conducted a lottery known as the golden casket, which has provided a total sum of over \$3,000,000 for medical "charities." It is interesting to note that of the total receipts from the lottery 53 per cent is returned as prizes, 20 per cent is absorbed in expenses, and 27 per cent is available for distribution. A considerable proportion of the money collected came from New South Wales and, in fact, all over the world.

In 1932, the New South Wales government, in face of considerable opposition from the churches, commenced lottery operations on its own account. The opposition has had the effect of curtailing the activities of the director of the lottery. No advertising is permitted and the tickets are limited to five shillings and three-pence. The Queensland lottery suffered when New South Wales commenced operations, but taking advantage of the restrictions fettering the latter, Queensland instituted a second lottery with \$1 tickets. Five of these were held, and \$50,000 in each was subscribed in New South Wales.

This has given considerable anxiety to the

minister of health and others, and demands have been made that the restrictions should be removed from the New South Wales lottery so that it may be able to withstand the competition. Statements have been issued in the press strongly defending the lottery on the grounds of expediency and urging that, since it is much less likely to cause ruin to the public than betting and horse racing, these should first be eliminated.

Another aspect of the lottery that is causing concern is the number of lottery shops that have sprung up. These sell one-seventh share in a ticket for a shilling, thus making a profit of 1/9 on each ticket. It is estimated that at least \$100,000 a year is lost to the lottery in this way. An attempt was made to prevent this practice, but on an appeal to the courts it was upheld as being perfectly legal. It is stated to be the intention of the state parliament at its next sitting to declare the sale of share tickets in this way illegal and also to prohibit the gift of shares in lottery tickets as bonuses to those buying goods in shops, at present a common practice.

In Queensland the sale of share tickets of one shilling upward has assumed the proportions of an industry. About every tenth shop in the state is engaged in this business.

As a means of financing capital and maintenance funds of hospitals, the lottery system is a definite success; but there is a strong body of "silent" opinion that is ashamed of the method.

THE CLINICAL SIGNIFICANCE OF THE PLASMA PROTEINS

WILLIAM S. McCANN, M.D.

From the Department of Medicine, School of Medicine and Dentistry, University of Rochester and the Medical Clinic of the Strong Memorial and Rochester Municipal Hospitals

The proteins of the blood plasma have functions of great clinical importance. They consist of two general groups, the *albumins* and the *globulins*, each of which contain several individual members. The globulins include *fibrinogen* which has special functions in the clotting of blood, in the exudations of inflammation, and in connection with the sedimentation rate of red corpuscles.

The albumins and globulins have most important functions in connection with the distribution and movements of fluid in the body. The blood plasma enclosed in the vascular system is separated from the interstitial fluids of the body by semi-permeable membranes consisting of the endothelial cells of the capillary walls. Normally these membranes do not allow the plasma proteins to pass across them, though water and dissolved crystalloids pass readily. Years ago the physiologist Starling pointed out the importance of the proteins of the plasma in maintaining the normal fluid exchange across the capillary wall. The hydrostatic pressure of the blood in a capillary tends to drive water and salts outward. The osmotic pressure of the plasma proteins tends to hold water in the capillaries. This osmotic pressure is such that it is intermediate between the blood pressure at the arterial and the venous ends of the capillary, so that a mechanism is provided for both outward and inward diffusion of fluid. When normally balanced, the volume of the blood plasma and interstitial fluids is very accurately regulated.

The balance between the forces maintaining plasma volume and interstitial fluids may be upset in a variety of ways: (1) by an increase in mean hydrostatic pressure in the capillaries, (2) by an increase in the permeability of the capillaries, (3) by a deficiency in the amount of plasma proteins in circulation. For instance, as examples of increased hydrostatic pressures: venous stasis, whether produced by heart failure, tourniquet, thrombosis, or in any other way, increases the outward diffusion and may result in one form of edema. The capillary

membrane may be injured in a variety of ways so that it allows plasma proteins to leak through. This not only results in a depletion of plasma protein, but it may also greatly enrich the protein content of the interstitial fluid, which further displaces the fluid equilibrium.

The degree to which the permeability of capillaries is increased may be roughly estimated by determining the extent to which the individual plasma proteins pass through them because these proteins differ as to their molecular size. For instance, the albumins have a smaller molecular weight than the plasma globulins, so that the finding of appreciable amounts of globulin in the urine or edema fluid indicates a greater increase in capillary permeability than if only albumin is found. Fibrinogen has a fairly large molecular weight, so that its escape occurs only in cases of severe damage to the capillary wall (inflammation). Bence Jones proteins are smaller than the plasma albumins and may escape more readily.

The size of the plasma protein molecules bears a close relation to their relative abilities to hold water. The serum albumin molecule is smaller than the globulin and has a far greater capacity to hold water. A depletion of the albumins of the plasma will more readily induce edema than a corresponding depletion of the globulins. Lepore³ has also made the interesting observation that the plasma volume is directly and closely correlated with the plasma albumin.

The third way in which the fluid balance within the body may be upset is through a deficiency in plasma protein, particularly of the albumin fraction. This often occurs as a consequence of excessive loss through abnormally permeable capillaries. It may also result from inanition. However it occurs, the result is a lowering of the colloid osmotic pressure of the blood plasma with an inevitable disturbance in water equilibrium.

Peters and Van Slyke⁴ give as normal values for plasma proteins the following figures: total protein 5.6 to 7.5 per cent,

albumin 3.4 to 4.9 per cent; globulin (including fibrinogen) 2.3 to 2.9 per cent; and the ratio albumin: globulin 1.4 to 2.0.

Inanition has long been known to be associated with dropsy, as Kohmann¹ demonstrated experimentally in 1920. Many data have been accumulated regarding the plasma proteins in states of inanition in various pathological states, which has been well reviewed by Peters and Van Slyke.² In this category fall the hypoproteinemias of diabetes, pernicious anemia, of carcinoma of the stomach, and similar conditions in which adequate nutrition is interfered with.

In the degenerative forms of Bright's disease, lipoid nephrosis, and the nephrotic stages of glomerulonephritis, the serum proteins are frequently found to be less than normal, particularly the plasma albumin. In lipoid nephrosis large amounts of albumin escape through glomerular capillaries into the urine. This amounts to a sort of "protein diabetes" in which the loss of albumin in the urine occurs more rapidly than the rate at which it can be regenerated in the metabolism. In glomerulonephritis both albumin and globulin may be diminished, though albumin is usually relatively more reduced than globulin. In this condition only a part of the loss occurs in the urine, as it seems probable that all the capillaries of the body are abnormally permeable, and protein loss to the interstitial fluid may be general.

A complete catalogue of conditions in which hypoproteinemia is found would be out of place in this brief paper, especially since the subject has been so recently and so well reviewed.³ The important thing from the standpoint of practical therapeutics is to take stock of our knowledge of the factors by which these proteins may be replaced or regenerated whenever they have been found to be depleted.

The first to attack experimentally the problem of determining the effect of diet on serum protein regeneration were Kerr, Hurwitz and Whipple.² These workers elicited the important facts that there were normal reserves of serum proteins, since they were found to be replaced during fasting after one or two initial depletions by plasmapheresis. They also found that the regeneration was more rapid if the dogs were fed liver rather than beef or milk protein. That the liver plays an important rôle in regenerating plasma protein was

shown by the delay in replacement after liver injury or Eck fistula.

Whipple² also showed that the fibrinogen of the blood was greatly reduced in the course of liver necrosis produced by chloroform.

Recently Lepore has reviewed all of the data regarding serum proteins in every case of recognizable liver injury observed on the Medical Service of the Strong Memorial Hospital over a period of 6 years. His findings have not yet been published, but they give indubitable evidence that injury to the liver beyond a certain point is associated with a lessening of the amount of serum albumin. In the more chronic forms of liver injury (cirrhosis) depletion of plasma albumin is observed long before the fibrinogen is decreased. The evidence that the liver plays a major rôle in the regeneration of serum albumin and fibrinogen is continually increasing. The mechanism governing the formation of the other globulins is far more obscure.

The problem of regeneration of depleted serum proteins in the nephrotic types of Bright's disease is one of great difficulty. The medical profession had first to rid its mind of the idea that a liberal use of protein in the diet was harmful. Gradually through the efforts of Epstein and others this fear was overcome. Keutmann and McCann³ have convinced themselves, at least, that no deleterious effects are observed in patients with glomerulonephritis to whom large amount of protein are given in the diet. In nephritis no evidence exists that the intermediary metabolism of protein is disturbed. The "wear and tear" quota does not appear to be abnormal. Protein may be stored in the body readily when given in adequate amounts and subjected to the sparing action of a liberal supply of carbohydrate and fat. In true nephrosis the regeneration of plasma protein may occur more quickly as a result of protein deposition than in the case of glomerulonephritis, for the reason that the protein loss in the former is chiefly through the kidneys, whereas in the latter a general increase in capillary permeability exists, which renders it doubly difficult to retain plasma proteins in circulation, even though the total deposition of protein in the body may be enormous.

Holman, Mahoney, and Whipple¹ have recently performed experiments of great significance. Dogs which were fed sugar

by mouth and given blood plasma by vein could be kept in nitrogen equilibrium, suggesting strongly that there is a give and take between plasma proteins and tissue proteins. Whipple has shown that total plasma protein decreases during starvation but that this is masked by a simultaneous shrinkage in plasma volume, so that the percentage of protein is not much altered. In some recent experiments in the writer's laboratory the plasma albumin of a dog fell steadily during experimental hyperthyroidism until the protein loss was stopped by an adequate increase in the diet.

It is known that plasma proteins cannot be increased above normal limits by high protein diets. Holman, Mahoney, and Whipple¹ have shown that intravenous infusions of plasma neither increase the plasma protein values beyond normal limits nor cause their excretion in the urine. In other words, it is probable that the phenomena of specific dynamic action of protein are brought into play to limit the deposition of protein once the normal reservoirs are full. It seems not improbable that a new conception of protein metabolism may develop, in which there is a fairly close analogy to that of carbohydrate. The reserves of plasma protein may bear the same relation to amino acids as the glycogen stores do to the blood sugar. The stores of plasma protein and glycogen may be depleted if metabolic demands exceed dietary supply. Both may be refilled when the supply is adequate. Overfilling of the reservoirs may be prevented by specific dynamic action in the case of protein, just as the overfilling of the glycogen stores is prevented by glycosuria and fat formation in the case of carbohydrate metabolism.

Little can be said about our knowledge of the factors controlling regeneration of plasma globulins. Whipple's experiments indicate that they are more easily regenerated from dietary sources than are the albumins. High globulin values are noted in connection with those conditions in which Bence Jones proteins abound, namely, leukemias and myelomas. High plasma globulins are also noted in kala azar.

In general the clinical evidence suggests that globulins may be produced either in the hematopoietic tissues or in the reticulo-endothelial system, but definite evidence is lacking.

In closing the most important fact for the practitioner to remember is that re-

generation of plasma proteins requires a liberal (not excessive) supply of good animal protein, and this must be supplemented by an adequate supply of carbohydrate and fats if protein deposition is to be secured. There is no longer any excuse for the protein starvation which has been practiced in the past in treating nephritis, high blood pressure, and arthritis since this starvation entails definite injuries resulting from a loss of the valuable functions of plasma proteins.^{2,7}

SUMMARY

1 Apart from the special functions of fibrinogen in exudation and blood clotting the major functions of the plasma proteins have to do with movements of water in the body, especially in maintaining a balance between plasma and interstitial fluid.

2 Starling's theory is briefly reviewed. Factors displacing the fluid balance are:

(a) Increased mean hydrostatic pressure in the capillaries. Venous stasis of heart failure, etc.

(b) Increased permeability of capillaries. Diffuse glomerulonephritis.

(c) Deficiency of plasma proteins, from inanition, nephritis, nephrosis, and hepatic cirrhosis.

3 Factors governing regeneration of plasma albumin are reviewed, insofar as they are known.

(a) Liberal sources of good animal protein, with amounts of carbohydrate adequate to secure deposition.

(b) The importance of the liver is shown by slow regeneration after liver injury, and by low plasma albumin values in hepatic cirrhosis.

(c) Factors controlling globulin formation unknown.

4 An analogy may be drawn between the relation of glycogen to blood sugar, and the plasma protein reservoir to amino acids. Depletion of the plasma protein reserve may be the result of inanition, or loss in the urine, or of any factors promoting a negative nitrogen balance. The reserve may be refilled by adequate nutrition. Overfilling is probably prevented by the specific dynamic action of protein.

CASE REPORT

AN UNUSUAL CASE OF TRAUMATIC PERITONITIS ASSOCIATED WITH ANAL PERVERSION

SAMUEL EPSTEIN, M.D., F.A.C.S.

From the Surgical Service of Lincoln Hospital, Department of Hospitals, New York City

Traumatic peritonitis is not an uncommon occurrence, but the circumstances surrounding the case to be presented are unusual. Also, of special interest are the x-ray findings taken before operation; for men with years of experience in x-ray work have never had the occasion to interpret such a plate as is shown in Fig. 1.

Fig. 1.—Flat plate of abdomen. Note star-shaped shadow in left pelvis representing core of apple.

The case is that of a male patient, age 54, married, who presented himself at Lincoln Hospital on October 7, 1932, complaining of abdominal pain, vomiting, and constipation. Patient was very uncooperative, but with the aid of the doctor who referred the case to the hospital the following history was finally elicited.

Two days prior to admission to hospital, the patient inserted two apples into his rectum. Various attempts were then made by the patient to remove those foreign bodies, but failing of success, he consulted a physician who succeeded in removing but one of the apples.

By this time, in addition to abdominal pain, the patient exhibited fecal vomiting. He was therefore referred to the hospital by the physician for operative treatment of intestinal obstruction.

PAST HISTORY.—This patient, it was discovered, though married and having raised a family has practiced anal perversion for many years. The records of Lincoln Hospital showed that about fourteen months prior to the present admission the patient presented himself for the removal of a cucumber from rectum. On January 7,

Fig. 2.—Above: X-Ray of the apple after removal from abdomen. Below: X-Ray of another apple.

1932, this patient was admitted to Morrisania Hospital, New York City, because of rectal bleeding, due to the presence of a stalked vegetable (a parsnip) in the rectum. This foreign body was removed under spinal anesthesia.

It is interesting to note that in both instances he gave a history of having been assaulted "has been overpowered by several men who forced the foreign body into his rectum."

Physical examination showed the patient to be well nourished, with anxious expression, and though he walked into the hospital, he appeared acutely ill.

Head, neck, and chest revealed nothing abnormal.

Abdomen was distended, tympanitic, and

tender throughout, suggesting the existence of a peritonitis.

The temperature was only 100° F., pulse 110, respiration 20, blood pressure 140/90. Examination of the blood revealed 20,000 white blood cells, with 87 per cent polymorphonuclears. The urine showed four plus albumin, four plus acetone, many hyaline and granular casts, and many white and red blood cells.

X-ray examination of the abdomen (flat plate, Fig. 1), showed that within the pelvis there was a star-shaped shadow within a circular shadow; the star-shape representing the core of an apple.

A proctoscopic examination was done prior to operation, and as will be seen later, proved misleading. The sphincter was markedly dilated, the anal and rectal mucosa appeared pale, and no foreign object could be detected.

A diagnosis of intestinal obstruction—mechanical in character—and peritonitis was made and patient was operated on five hours after admission to hospital.

On opening the abdomen it was found that the peritoneal cavity was filled with dirty-colored fluid, apparently soap suds given in enemas prior to admission to hospital. The apple, 2½ inches in diameter, immediately presented

itself, lying just above the brim of the pelvis surrounded by loops of small intestine and omentum which were greatly edematous, markedly congested, plastered together, and covered with fibrin. The entire peritoneal cavity showed an extensive generalized plastic peritonitis. At the rectosigmoid junction there was a rent in the anterolateral surface of the bowel, measuring about 2 inches in diameter. (The proctoscope evidently passed by the rent in the bowel wall unnoticed.) The mucosa was pale, there was no evidence of any recent bleeding or ulceration.

The abdominal cavity was cleansed, the rent in the bowel was closed by rows of continuous mattress and Connell sutures. Iliostomy was performed to drain the bowel above and the abdomen was closed with two cigarette drains.

The postoperative course was short, ending in death two days later.

An autopsy was performed and the following is the medical examiner's report: "An extensive plastic peritonitis with moderate distention of the intestines is present. A large area in the anterior aspect of the upper rectum and lower sigmoid is discolored and sutured. There is no evidence, microscopically, of persisting perforation. Generalized peritonitis seemed to be the cause of death."

1882 GRAND CONCOURSE

TO PREVENT MALPRACTICE SUITS

After a searching inquiry into malpractice suits in Minnesota, the Medical Society of that State publishes the following suggestions for preventing these troublesome actions: x-ray all injuries; follow up all cases started; advise lockjaw serum in all injuries, even a scratch; don't attempt too much—call a consultation if it seems in the least advisable; follow standard treatment; inform the patient of all possibilities; carry a good protection policy; more ethical practice among doctors; stop criticizing other

doctors; less jealousy among doctors; every M.D. should belong to his medical society; unity in the medical profession; closer social relations with honorable attorneys; educate the doctor to do better work by postgraduate work in the different societies; do your best in every case and be careful; doctors talk too much; more care; no distinction between competent and incompetent physicians; publish names of physicians who testify against fellow physicians; expel doctors who testify against other doctors.

DR. MAYO ON THE DOCTOR'S RELIGION

Religion is a loose and indefinite term, and may range from the faith of the devout ascetic to the fanaticism of the head hunter, but if the patient is to have faith in the doctor, the doctor, in turn, must have faith in something. That is the argument of Dr. William J. Mayo, who says in the *Epworth Herald*, in an interview: "The good doctor may not be orthodox, but he is fundamentally a religious man."

"There is a tendency of the times for a group of intellectuals, that is, persons who have been educated beyond their intelligence, to underrate the value of religion as the universal comforter in times of physical or spiritual stress, but to the mass of the people, religion has the same potency that it has had for two thousand years. The sick man needs faith, faith in his physician, but there comes a time when faith in a higher power may be necessary to maintain his morale and sustain his emotions. I do not know how the doctor can strengthen that faith unless he himself knows and practices the values of religion, not necessarily the creeds and

dogmas of any particular church."

This sentiment is endorsed by the *Journal of the American Institute of Homopathy*, which seems to define religion in terms of service, as it observes: Above all, in his work the doctor needs religion. The easing of a patient's mind, if not at times his cure, depends largely upon his confidence in his medical advisor, and that confidence will be inspired more often by what he senses of the spirit of his doctor than by what he perceives of acumen in advice. Few of us are such perfect actors that we can keep from our facial expression and tone of voice the contradictions which will destroy the effect we desire, unless the feeling within is kindled by the fires of inspiration.

From his work the doctor also partakes of religion. If there is any greater happiness in this world, for any individual, than the knowledge that he has been instrumental in relieving suffering and in making another mortal's travail easier, we have yet to find it. Such happiness is the very essence of religion.

EDITORIALS

The Election in November

The medical profession should vote at the forthcoming election. It should cast its vote intelligently. As citizens we are interested in good government. We are not at all concerned with politics. The medical profession is vitally concerned with the protection of the public health. Naturally it is opposed to any and all measures that hamper the programs of health officials and of medical progress. It therefore opposes any interference with those who carry out health preventive measures such as vaccination against smallpox. It desires to continue to probe for the secrets of bodily disease and find successful measures to heal the sick, and needs uninterrupted opportunity to make studies upon dogs and other animals to accomplish these ends. The profession desires of itself to evolve a better medical service to the communities it serves, taking into account the changing times of this era. It desires to maintain the principles and arts of private medical practice. It desires to remain uncontrolled by either government, lay groups, or philanthropic foundations.

It is desirable that the physician should consider the candidates for public office, not only in the light of their intelligence and integrity, but also from the standpoint

of their comprehension of the conditions of medical practice. The profession is deeply concerned in maintaining the high standards enacted by the legislature for professional licensure. Each candidate should be queried as to whether he is opposed to animal experimentation; whether he would license any of the irregular healing cults, whether or not he would favor the payment of physicians for dispensary service and would favor an attempt to put an end to the abuses of medical charity. The profession should ascertain the candidates' stand on compulsory health insurance, and whether or not he favors the desire of the profession to remain master in its own house.

No physician in these times should cast his ballot blindly. Vote so that your ballot speaks for you.

Medical Care for Indigents in New York State

Responsibility of a community to provide medical care to its poor as well as food, shelter and clothing has crystallized into general recognition in recent years. The citizen "in need" should find medical attention readily available; and the machinery of administration by the community should be so simple, so easy to understand, so soundly arranged that all concerned, sick man, physician, community welfare official can go into action, separately and collectively, *quickly and surely*.

Legislative enactment for regulation of provision of medical care to the poor and needy in New York State has been an evolutionary process, usually motivated irregularly and independently by minority groups toward more or less solitary objectives. The gradual accretion of law has followed no comprehensive and inclusive master plan. Orderly progress to co-ordinated effective action between the necessary agencies has not developed. Chaos, conflict, deficiencies, overlapping provisions and other faults confront and confuse those who should participate and co-operate understandingly. Ten different statutes and fragments of others, prescribe how public and semi-public assistance shall or may be given to the poor in need of medical care.

Under such conditions, how could medical service be furnished the indigents smoothly, easily, efficiently in accordance with the simple, all inclusive formula, "quickly" and "surely"? And in New York State this formula, in fact, is not satisfied.

For a long time aware of the situation, the Medical Society of the State of New York commissioned its Committee on Economics to delve deeply into this phase of the larger problem of providing medical care to all citizens of the State, with a view to formulating positive suggestions, positive plans that should do full justice at one and the same time to patients, taxpayers and physicians, now and in the future.

The first step has been taken in the field of medical care of indigents and completed during the last summer. Those parts of the laws which specify the actions, powers, privileges and restrictions, responsibilities and authority of those concerned with the administration of the laws or with the actual task of medical care have been extracted, briefed, published in a loose-leaf book of 121 pages. Copies have been circulated among physicians, County Societies, nurses, officials of welfare, health and hospital positions, with a request that each recipient note on blank interleaves personal comments on deficiencies, on conflicts, on needs for correction in the laws. When these annotated books return the Committee will classify and analyze the criticisms. Conferences may be held with those agencies both State and local having to do with various provisions of the laws relating to the indigent especially as concerns provision of medical care and hospitalization. Two objectives are being pursued. The one is simplification by amendment of the laws where necessary, the other, publication of a manual which shall guide all concerned with provision of medical service, be it casual or custodial care, to the poor and needy.

At this time, when revolutionary changes are being proposed from outside the profession, it should be enheartening to know that the State Society is actively moving toward carefully considered action, that it has advanced with due study and fore-

sight along the first most important pathway, medical care for indigents.

The Journal urges all those who have received this book for review, all those who will next receive it, to study, annotate and return it at the earliest moment. In their hands rests the success of this effort.

Doctors, Dollars, and Disease

Many of our profession have recently received a little booklet, telling of an "educational" venture by the National Advisory Council on Radio in Education. This series of lectures is to be broadcast to the nation and can also be had for a small sum of money.

We concede the necessity of education in medical economics and would applaud any impartial instruction or even debate on topics concerned with private practice and with compulsory health insurance. We would particularly recommend report concerned with the economic aspect of the cost of community health insurance to the taxpayer. We would like to hear discussed by competent authorities who know American physicians as we do, what effect such a program would have on the way government employees would vote, and what the effect of their common interest in the taxpayer's money would do to the taxpayer. But the schedule consists of nineteen lectures by nonmedical men who want to tell medicine how to "carry on." Of the seven speakers who are physicians, two are avowed protagonists of health insurance; one is a president of a university which graduates doctors of medicine and runs a pay clinic in competition with them; and a fourth is a former president of the American Health Association whose interests have always been in that sphere. Actually there is but one of the physicians selected who by any stretch of the imagination can be termed a representative of the viewpoint of practicing physicians.

The majority of the lecturers are directly associated with foundations actively working for compulsory health insurance. Three are officials of hospital associations and the remaining five embrace a public health nurse, a journalist, two investigators in the field of public health and a professor of industrial relations.

The medical profession should make its protest felt against this misuse of the educational function which the Federal Radio Commission has placed in the hands of this National Council on Radio Education.

The Medical Horizon

The profession is awake to the changing times. It has begun to experiment with means to evolve a plan of medical practice which shall maintain the priceless relationship between physician and patient and yet make concession necessary to the new order in the changing era.

The propaganda emanating from the Milbanks, the Filenes and the Rosenwald groups has influenced some parts of the lay public and some of the press into the belief that the profession was "reactionary" and acted as "obstructionists" to any changes. The profession would be considered "liberal" if they only would accept the hypothetical conclusion arrived at by the numerous PH.D.'s who are engaged in attempting to change medical practice, "for the welfare of mankind."

In government circles, two of the Milbank people are delegated as a Committee on Economic Security to develop the medical side of this security. The profession has not even been asked to co-operate; and propaganda is flooding the country emanating from the National Advisory Council on Radio in Education.

Meanwhile, in California, the Alameda County Medical Association has plans in operation to provide medical care for persons with small incomes. In Oregon there are physician controlled health associations which are working out schemes in the furthering of economics approved by the county societies in their localities, and these service units are working throughout both Oregon and Washington. In Detroit the Wayne County Medical Society is engaged in a project which also promises success. In New York the principles enunciated in the Booth Report two years ago are finding practical expression through efforts to provide hospital care for those who are below the comfort level without disturbing the principles of private practice.

The American College of Surgeons contrary to distorted news reports has done nothing radical or blazed any new trails in

its recent declaration of policy. The president of the College says,

"In a country of so many diverse elements as those which make up the United States of America with the population here crowded in great industrial centres, there scattered in agricultural districts and in other places more widely distributed still over the practically unsettled and frontier districts of the North and the West, it is not to be expected that any single national plan for providing medical or surgical service to the whole community should prove everywhere to be satisfactory. The problem is essentially a local one to be studied and solved by the members of the individual communities and by trial and error, if by no other means. In these experiments it is of vital importance that the medical profession should take the lead."

This is not advocating health insurance, nor does it constitute a striking departure of the principles formulated and passed by the last House of Delegates of the American Medical Association.

The profession has never taken the stand that the existing system of providing medical care is perfect and that it would tolerate no change. On the other hand, it points with interest and pride to its own practical endeavors in many county societies where it has achieved appreciable reforms and where it promises to serve the needs of the communities entrusted to its care far better than either voluntary or compulsory health insurances could ever hope to do.

Organized medicine envisages its horizons, sees the propagandist who would wrest medical control from professional hands and opposes this with all its strength. It will throw its strength behind any reform whose benefits are demonstrable by reason or experience. It cannot accept experiments or experiences based upon findings in foreign lands, where compulsory health insurance delivers a service inferior in many respects to that which our indigents receive here.

The profession will not sacrifice medical standards, high quality of service and professional independence for results which where tried are not comparable to those of the existing American system.

News

of Interest to the Profession

LABORATORY AIDS IN THE DIAGNOSIS OF AMEBIC DYSENTERY

Issued by The New York State Association of Public Health Laboratories, August, 1934

More than 1 year ago (January 1, 1933), the NEW YORK STATE JOURNAL OF MEDICINE published a condensed report on the use of laboratory facilities by practicing physicians in New York State, which had been made by a special committee of the New York State Association of Public Health Laboratories. This association is composed of representatives of laboratories approved by the State Commissioner of Health. A separate and independent organization, it has collaborated effectively with the Division of Laboratories and Research of the State Department of Health in the development of laboratory service in the State. Thus, it is customary to refer many matters of policy or procedure to the Council of the Association for its opinion before action is taken. As one of the direct results of the recommendations of the Committee on the Use of Laboratory Facilities, a series of leaflets on laboratory aids in diagnosis is being issued by the association for distribution by the local laboratories represented in the association to practicing physicians in their districts. The leaflets are brief and practical, and are intended for convenient and ready reference. Two, on undulant fever and on typhoid and paratyphoid fevers, have already been reprinted in the JOURNAL. The third leaflet, "Laboratory Aids in the Diagnosis of Amebic Dysentery," is now published.

The clinical manifestations of amebic dysentery may range from a fulminating onset, tenesmus, abdominal pain, frequent discharges of blood and mucus marked toxemia, and death within a few days from intestinal hemorrhage or perforation, to a condition of seemingly mild, recurrent diarrhea. Symptoms suggestive of appendicitis may be present. Many symptom free carriers harbor cysts in the colon and are capable of spreading the disease. Amebic and bacillary dysentery are often so much alike in their acute phases that differentiation is possible only by laboratory examination of the stools.

The effectiveness of treatment depends upon early diagnosis and prompt institution of the specific therapy. Early treatment also reduces the likelihood of the serious complication, amebic abscess of the liver. Chronic cases are far more resistant to remedial measures than recent ones.

SUBMISSION OF THE STOOL SPECIMEN—Diagnosis of amebic dysentery may be made by finding in the stool either the actively motile vegetative form of *Entamoeba histolytica* or the characteristic cysts. In submitting laboratory specimens, the following points should be considered, but it is always desirable as an initial step to consult the local laboratory director.

- (1) The stool must be fresh. This is essential, since the amebae may disintegrate soon after the specimen cools to room temperature. If possible the patient should pass the stool at the laboratory, if not, the stool should be col-

lected in a warm container, kept warm, and sent immediately to the laboratory. (2) The entire stool should be submitted, if this is impracticable, the specimen should include some of the bloody mucus. (3) Cysts are much more resistant and may be found twenty-four to forty eight hours after the stool has been passed provided it has not been allowed to dry. (4) Examinations on six successive days may be necessary to demonstrate the presence of amebae although three examinations are usually sufficient. (5) If no amebae or cysts can be demonstrated in stools passed spontaneously, a more satisfactory specimen may often be obtained by using a sigmoidoscope and scraping off with a small spoon curette a little necrotic material from the bed of an ulcer. (6) No oily medication should be given before collection of the specimen because oil droplets make examination for amebae difficult. (7) Since relapses are very common and may occur more than a year after an apparent cure, it is important to have specimens examined monthly for at least twelve months after symptoms have subsided.

EPIDEMIOLOGY—Despite the recent water borne epidemic in Chicago, the chief factor, apparently, in the spread of amebic dysentery is usually the presence of encysted amebae in the stools of convalescents or healthy carriers hence the predominantly endemic rather than epidemic occurrence of the disease. The carrier who is a food handler is a special menace. The disease is essentially one of tropical and subtropical climates but competent protozoologists believe it is far more frequent in temperate zones than is commonly supposed. It is probable that infection rarely results from the ingestion of the vegetative forms, they are promptly destroyed by the digestive juices.

THE GROWING PROBLEM OF MENTAL DISORDERS

An increasing number of the physician's patients, year by year, are found to be suffering from some sort of mental upset, and it is becoming more and more important that the doctor shall carry in his equipment a knowledge of the latest findings and refinements of psychiatry. The cold figures are, in fact, well high appalling. The number of mental patients in state hospitals in this country amounted to 32,000 in 1880, in 1910, the figure had risen to 160,000, in 1929, to over 272,000! Putting it another way, 63.7 per 100,000 of the general population were mental patients in 1880, while in 1929 the figure had leaped to 225.9.

These startling figures were cited by Dr Frederick W Seward, Jr., of Goshen, N. Y., in a paper read at a medical meeting in New York City to show that every physician should become more familiar with the com-

plexities of obscure mental disorders and their problems. Any family under the physician's care may produce a case where mental trouble plays a part. The diseased mind may develop a criminal trend, it may descend into feeble-mindedness, it may lapse into the confusion of insanity, it may sink into suicidal melancholia, and the family doctor is the one who has to diagnose the case and decide what is to be done. It is he who must foresee the sudden homicidal impulse, or the desire to leap from the window, and forestall it. He knows that the appendicitis case should go to the hospital, he should also know when the mental case should go to the mental hospital.

Diagnosis is often difficult, Dr. Seward points out. A wide variety of presentations appear in psychoneurosis. We meet with hysterical episodes, repressed wishes, mental conflicts, emotional experiences that temporarily break through and dominate the mind. We meet with anxieties, obsessions, morbid fears, feelings of insufficiency. Such cases can be very well treated by the general practitioner, although, of course, if he finds he is making no progress, he can turn them over to a psychiatrist. Some are better off in institutions, some are helped by psychoanalysis, some require a change of environment—each one is a problem by itself. One thing Dr. Seward would stress: a psychoneurosis case is not a "nervous breakdown." It is mental and must be so classified, or confusion results. And while speaking of classification, it may be helpful to mention that the Department of Mental Hygiene at Albany publishes a guide that contains a complete classification of mental disorders

and a brief outline of each, together with other information. It might well be kept in a desk drawer for ready reference.

The field of psychiatry is growing with amazing rapidity. The cases are multiplying so fast that their study is forced upon the doctor's attention, whether he wishes it or not. They have grown to be not only a medical but a social problem of national magnitude. It has become a field that no physician can neglect.

ANNUAL CONFERENCE OF COUNTY SOCIETY SECRETARIES

At the conference in Albany, on September 11, 1934, a round table discussion was staged on the medical aspects of administration of the welfare laws. Three guests with expert knowledge and clothed with the authority of their official positions were invited to come prepared to answer questions. Dr. H. Jackson Davis, Director of Medical Care, State Temporary Relief Administration, Mr. Clarence E. Ford, Assistant Commissioner, State Department of Health, and Mr. F. A. MacIntyre, President of the State Association of Public Welfare Commissioners, gave generously of their time. Written questions had been framed in advance designed to clarify various points and one or other of the visitors was asked to reply to each query. The full detailed minutes will be found in this issue.

In connection with the Manual issued by the TERA (mentioned in the minutes) these questions and answers should be of real value for reference.

MINUTES

ANNUAL CONFERENCE OF COUNTY SOCIETY SECRETARIES MEDICAL SOCIETY OF THE STATE OF NEW YORK

Hotel Ten Eyck, Albany, September 11, 1934

The following County Societies were represented:

Albany.....Dr. Nelms
Bronx.....Dr. Friedland
Broome.....Dr. Lape
 (Substitute)
Cattaraugus.....Dr. Garen
Cayuga.....Dr. Chidester
Clinton.....Dr. Schneider
Cortland.....Dr. White
Delaware.....Dr. Thomson
Erie.....Dr. Beamis
Genesee.....Dr. Di Natale
Greene.....Dr. Rapp
Kings.....Dr. Elliott
 (Substitute)

Livingston.....Dr. Doolittle
Madison.....Dr. Mills
Monroe.....Dr. MacVay
Montgomery.....Dr. Pierce
Nassau.....Mr. Neff
 (Executive Secretary)
New York.....Dr. Dougherty
 Dr. Irving
Oneida.....Dr. Hale
Onondaga.....Dr. Mack
Orange.....Dr. Shelley
 (President)
Orleans.....Dr. Roach
Oswego.....Dr. Brennan

Rockland.....Dr. Richards
(President)
Schenectady.....Dr. Cravener
Schuyler.....Dr. Ward
Seneca.....Dr. Lester
Sullivan.....Dr. Payne
Tioga.....Dr. Peterson
Washington.....Dr. Banker
Westchester.....Dr. Brillinger

Others present were: Drs. Bedell, Albany, President of the Medical Society of the State of New York; Podvin, Bronx; Hicks and Stover, Amsterdam; Conway and Lawrence, Albany; also, by invitation, Dr. H. Jackson Davis, Director of Medical Care, State Temporary Emergency Relief Administration; Mr. Clarence E. Ford, Assistant Commissioner, State Department of Social Welfare; and Mr. F. A. MacIntyre, President, State Association of Public Welfare Officials.

Dr. Dougherty, as State Society Secretary, had announced, when the first invitations were sent out to the secretaries, that the general program would be a round-table discussion of the administration of the Welfare Law, and asked that the Secretaries submit to the Executive Officer in writing requests for clarification of any part of the law or its administration. To assist in the conference, Dr. Davis, Mr. Ford, and Mr. MacIntyre were invited to be present to give their expert opinion in answer to these questions.

The conference was called to order by Dr. Peter Irving, Assistant Secretary of the Medical Society of the State of New York, at 10:10 A. M.; Dr. Joseph P. Garen, Secretary of the Cattaraugus County Medical Society, was elected to act as chairman of the conference. Dr. Garen first called upon Dr. Arthur J. Bedell, President of the State Society, who spoke as follows:

Mr. Chairman and Gentlemen: It is a pleasure to meet with you this morning and to extend to you our hearty welcome, for upon your activity, interest, and knowledge much of the success of the County Societies' endeavors depends. You will in all probability devote considerable time to economic problems, but before you concentrate, there are certain questions that I would like to ask you and wish you would, by raising your hands, indicate whether or not the information I ask is on file in your office and is available to the members of your Society:

First: Has your County Medical Society accepted the terms of an agreement made between the State Medical Society and the State Emergency Relief Administration?

Answers in affirmative: Seneca, Madison, Nassau.

Second: Those of you who have not done so, have you entered into modified agreements with a County Emergency Relief Administrator? And those of you who did not

enter either of these two groups, to what extent have you refused to cooperate with the County Relief Administrator?

Answers in affirmative to first part of question: Bronx, Tioga.

Third: Has your County Society designated representatives who can act for them in cooperation with the local emergency relief administrator to adjust difficulties as they arise?

No answers.

Fourth: Have you in your County Society any definite plan of medical service for indigent transients?

Answers in affirmative: Erie, Onondaga, Monroe, Genesee, Seneca, Nassau, Westchester, Cattaraugus, Livingston, Sullivan, Bronx.

Fifth: Has there been any change in your county in the method of giving medical service to those unable to pay for it?

Answers in affirmative: Clinton, Seneca, Schenectady.

Sixth: Have you any criticisms of the administration of the Federal Emergency Relief Administration medical services?

Answers in negative: Greene, Erie, Genesee, Bronx, Seneca, Westchester, Rockland, New York, Cattaraugus, Monroe, Nassau, Tioga.

Dr. Lawrence was then called upon to read the questions that had been received, referring each question to one of the three guests for answer.

The questions and their answers follow:

Question 1: Please describe the procedure to be followed in providing medical care to the indigent; in the rural districts; in the cities.

Answer: MR. MACINTYRE: It strikes me that this is a question that might occupy all the forenoon in answering. Some of the doctors whom I employ are twenty-five and thirty miles away from my office. The patient in question may be several miles from the doctor's office in either direction. I have, therefore, had an understanding with the doctors that when they are called by an indigent patient that they are to go, and that we are to fight out later the place of settlement of said patient. I mean by that, find out later as to what town or county the patient may belong. I tell the doctor to treat the patient exactly as he would a patient in whose family he has already been employed. There are certain rules, of course, covering what charges he can make for which the town or county can be reimbursed. If a doctor has to drive a good many miles or go out in the night, it is understood that he is to be paid more than the reimbursable charge. I then ask him to

render me two bills—one that is reimbursable and one that is not.

Question: Is the procedure any different in the cities than in the county?

Answer: MR. MACINTYRE: That question I cannot definitely answer, since each city has its own set-up as allowed under the terms of the Public Welfare Law. Some have regularly appointed physicians employed by the day, month, or year.

Answer: DR. DAVIS: On page 46 of the Manual* you will find the exact legal procedure which Mr. MacIntyre outlined. The difference between county and city will be found on pages 48 and 49.

Question 2: Please describe how a man injured on a TERA work contract is to be cared for? If he requires hospitalization who authorizes and who pays for it?

Answer: DR. DAVIS: The procedure is different from the handling of other cases only at the time of injury. The foreman in charge of the job has the responsibility for seeing that a man gets the necessary first aid and immediate attention, and the first thing he does in the way of reference is to turn the whole case over to the local commissioner of public welfare or to the person who is in charge of home relief. A man injured on work relief is under work relief provisions only so long as he is working. If he becomes injured the whole matter is turned over to the person directly responsible for giving medical care through home relief channels. As you will recall from the Act itself, the name of that section is a work relief disability allowance. The interpretation was made very simple so that the man who is injured on a work relief project, instead of getting two-thirds of his pay or whatever percentage he would get under the usual disability compensation provisions, immediately goes on his full relief budget for his family, so the amount that he gets is enough to cover all the needs of his family.

The welfare commissioner is the man ordinarily responsible for hospitalization. There are one or two exceptions; in one or two counties where they have a combined work relief and home relief set-up there has been a division of duties. In these instances the man who is in charge of combined work relief and home relief set-up is responsible for all services except hospitalization. The commissioner of public welfare is in charge of the hospitalization fund and he authorizes that hospitalization. Whoever is responsible for the usual orders for hospitalization with regard to any indigent person in the State

is responsible for that sort of authorization in injury on work relief. This is paid for locally and subject to 75 per cent reimbursement by the TERA.

(See the Manual, Chapter III, Section A, Item 3, pages 42 and 43; and Section 85 of the Public Welfare Law, page 47.)

Question 3: How is medical care provided for the old-age pensioner?

Answer: MR. FORD: By the county commissioner, in the same way he provides medical care for persons not eligible for old-age relief. One-half is paid back to the locality by the State. The rates paid by the public welfare district to the doctor for old-age security cases vary somewhat in the several counties and are not fixed by the schedules of the TERA.

Question 4: How can one secure nursing service for the aged?

Answer: MR. MACINTYRE: It usually happens that there is some good, kindly woman in the immediate neighborhood who has had experience in practical nursing. I have never had any difficulty at all in this matter. Some of the aged make their own selection of a nurse and we pay the bill and charge it to "Special Relief" as we are allowed to do under Chapter XIV-A of the Public Welfare Law. In case the aged person is very ill, or gives promise of being ill over a long period, we commit him to a hospital. It is understood in our county (Madison) that after a person's hospital bills reach \$65.00, further costs will be a charge upon the town of his immediate settlement.

Question 5: Does the TERA provide any medical care without the welfare officer's assistance?

Answer: DR. DAVIS: Not except through work relief. The TERA provides no home relief services directly. All medical care is authorized and paid for by the local welfare officer who is responsible, under the general provisions of the Public Welfare Law. (Note especially Section 83, reprinted on page 46 of the Manual.)

The local welfare officer authorizes and pays for all expenditures for home relief. The TERA is a special agency of the State designed to assist the local communities in the provision of more adequate relief. Such of the authorized services and expenditures provided by the local welfare office which comply with the restrictions imposed by the Emergency Relief Act and the Rules of the Administration may be eligible for reimbursement by the TERA. Such reimbursement is but another name for State Aid.

Question: DR. LESTER: What about an indigent veteran in home or hospital?

Answer: DR. DAVIS: In so far as authorized care comes under the TERA rules, it is handled in the same way as care for a regular relief case. "Relief for veterans under exist-

* References made by Dr. Davis to "The Manual" in his answers refer to the printed "Manual of Rules and Regulations Governing Medical Care Provided in the Home to Recipients of Home Relief." Issued in June, 1934, by the Temporary Emergency Relief Administration, 79 Madison Avenue, New York City.

ing laws" was excluded from the scope of the TERA in the original Emergency Relief Act (Chapter 798 of the Laws of 1931). However, such relief was included in home relief by an amendment to this Act on May 1, 1933 (Chapter 646 of the Laws of 1933). Home relief for veterans is now included and handled in the same way as all other relief. (See the Manual, Section A, Item 2, page 42.)

Question 6: Is it possible to eliminate the offices of city physicians and surgeons under the TERA so that the local family physicians might take care of city indigent or welfare cases and get paid something, rather than have the city physician take care of them at a loss to the family physician both monetary and perhaps loss of patient ultimately?

Answer: DR. DAVIS: It is possible, yes. It has been done in one or two instances. The position the Relief Administration has taken is that the TERA fund is an emergency fund to assist in meeting additional burdens placed upon local communities by the depression. In order to consider a request for a change, eliminating salaried physicians from the local set-up, it is necessary first to submit adequate evidence that the service is inadequate; in other words, that the number of visits made by the city physicians, in relation to the compensation which they receive or in relation to the amount of work which one man can do, is such that according to reasonable standards these people who are being cared for cannot be given adequate care. In order to demonstrate this we have asked for records for preceding years to show the increased burden. If the request is accompanied by such records and it is demonstrated that the services available are not sufficient to give adequate care, one of two things can be done—a restriction may be placed upon the activities of the city physicians; they may be confined to a certain type of service, such as care for transients, a certain restricted group of home visits, and the remaining visits to indigents may be opened up to the individual physicians. Another way is a complete change opening up locally participation in the medical relief program. The position that the Administration has taken is that actual figures shall be supplied by the public authority responsible for supervising that work, as evidence for a change. Legally the TERA cannot act unless they have that type of information. (See the Manual, Section D, Item 1a, page 11; Section E, Items 2 and 3, page 13; Regulation 13, page 41.)

Question 7: What is the procedure to be followed in securing hospitalization for an indigent?

Answer: MR. FORD: There are two classes of hospitalization, emergent and non-emergent. First of all, in the emergent case, the hospital is required within forty-eight hours

to notify the welfare officer and, second, to accompany that notice by a certificate from the physician in charge saying that the case is an emergent one. When that has been done there has been a difference of procedure. We have gotten an opinion from the Attorney General to the effect that the welfare officer apparently is obligated to accept that case as a public case until he rejects it. There has been complaint both from the doctors and hospitals that after they have had these cases for a month or two they are finally rejected and no one gets anything. The second class includes those that are non-emergent. In those cases the responsible welfare officer should be consulted before the case goes to the hospital, and if he accepts the case as a public charge, then he arranges for hospital care and for the physician if he is employing the physician. If, as in some hospitals, no medical service is paid for from welfare funds, then the hospital takes care of the medical end of it. The welfare officer may or may not, in his discretion, employ the man who has been attending the case. He is under no obligation to do so and the man who has been attending a case for as long as five years may lose the case if the welfare officer so directs and the person is being cared for from public funds.

Question: DR. ELLIOTT: Does the welfare officer who, having a case in need of hospital care, transfers that case to a hospital in another district with a communication that he will be responsible for the hospital expense but not for the doctor's fee, act within the intent of the law?

Answer: MR. FORD: In my opinion, he is not acting within the intent of the law, as provided in Section 83, which reads: "RESPONSIBILITY FOR PROVIDING MEDICAL CARE. The public welfare district shall be responsible for providing necessary medical care for all persons under its care, and for such persons otherwise able to maintain themselves, who are unable to secure necessary medical care, except in so far as, in cases of communicable disease, that duty may be imposed upon the health officer by law or the State Sanitary Code. Such care may be given in dispensaries, hospitals, the person's home or other suitable place." I should say, answering your question, that while the law does not specify exactly what he shall provide, yet manifestly he is not carrying out the full intent of the law except in cases where the hospital prefers not to have medical fees paid.

Question: DR. ELLIOTT: What can the doctor do to prevent such unfairness?

Answer: MR. FORD: The only thing I can think of that can be done is that the doctor enlist the support of the hospitals in informing the welfare officer that they will not take care of cases unless medical care is provided. A hospital can do this better than a doctor.

The doctor should also discuss the situation with the welfare commissioner.

Question 8: Why should not the welfare commissioner pay for services rendered the indigent in hospitals?

Answer: MR. FORD: No reason, and I have held to the position before local Medical Societies that there is no reason at all why a doctor should be expected to give free care to indigent persons. Nobody else does it and the principle of paying the doctor has been recognized under the TERA act.

Question: DR. PODVIN: How or in what way can that be made to apply in cities like Albany or New York, where a majority of the indigent are cared for in city hospitals or clinics?

Answer: MR. FORD: The situation is a bit different in New York and Albany. Albany has no municipal hospital but cares for the indigent by arrangement with incorporated hospitals. In New York City there are both types of hospitals, but most of the indigent are cared for in the public hospitals. In New York City the situation could be changed by changing the city charter and in no other way. You know the procedure in changing a city charter. Here in Albany and in other cities of the same type it is less difficult; no amendment to the city charter or law is required, merely an arrangement with the city government and the doctors who practice that the doctors will be paid. That will require a change of heart on the part of city administration.

Question 9: Injured employee on TERA project, when taken to a hospital, doctor's bills not allowed: why?

Answer: DR. DAVIS: Probably because the physician's service was not authorized through the regular channels. The care of people injured on work relief projects is no different from any other authorized medical care except that it extends in scope into hospitalization and emergency care for persons certified by the foreman as injured in the course of duties connected with work relief. These are the only two exceptions.

Question 10: If an old-age pensioner is afflicted with a chronic disease that compels him to be a bed patient, what should be the procedure to secure it?

Answer: MR. FORD: The statute provides that old-age security allowance shall be for those who are not in need of institutional care. If a person is confined to bed, decision rests with the welfare commissioner as to the need for such care. If the person goes permanently to an institution old-age allowance ceases. If he is cared for in his own home or otherwise, then the arrangement for the medical care is made with the county commissioner, but the county commissioner may at any time order the case to go to the

county home or other institution and, if he does, the old-age allowance ceases and the doctor is paid only for such visits as the commissioner has authorized.

Question: Old-age pension authority ceases when the patient leaves his home?

Answer: MR. FORD: Yes, except for temporary care in a hospital. In those instances it is up to the commissioner, in cooperation with the State Department of Social Welfare, to decide whether care is likely to be temporary or permanent. If temporary and the welfare commissioner authorizes payment by the public welfare district, one-half is paid back by the State for the service rendered by both hospital and physician.

Question 11: Why should not the doctor be allowed the regular fee under the TERA?

Answer: DR. DAVIS: The TERA has nothing to do with fees. Any bill paid by the welfare commissioner which complies with general rules is eligible for reimbursement up to basis stated in these rules.

Question: DR. ELLIOTT: Is it not true that the TERA has a schedule of fees on which they base reimbursement to the local authorities?

Answer: DR. DAVIS: We have a basis on which to reimburse. Please note on page 29 in the Manual, Regulation 9, which reads as follows:

"Schedule of Reimbursable Charges. Introduction. *a.* It is realized by the Administration that with the funds available, it is impossible to compensate fully the physician, dentist or nurse for his or her professional services. The following schedule of charges, therefore, should not be considered as complete compensation for services rendered, but rather as a maximum basis for reimbursement, with due consideration for the conservation of relief funds to the mutual benefit of the patient, the professional attendant and the taxpayer.

"The following schedule of reimbursable charges was prepared following a conference in Albany, N. Y., on April 16, 1934, between authorized representatives of: the Medical and Dental Societies of the State of New York; the Administration and the State Commissioner of Health.

"*b.* The charges listed are hereby established by the Administration as the maximum eligible for reimbursement under these Rules and Regulations. However, no statement in these regulations shall be construed to prevent a local commissioner of public welfare: from making additional payments, for specified services, from local funds;* or from making payment at less than the maximum charges stated in these regulations, where the local professional organization has agreed to the

* Under Section 83 of the Public Welfare Law, see Chapter III, Section C.

authorization of specified services at a lower rate."

Question 12: Has the TERA an arrangement with the welfare officer to reimburse him from State funds for certain purposes? How does this affect agreements between the local welfare officers and the local Medical Societies?

Answer: DR. DAVIS: I shall cite an example: In the City of Port Jervis the welfare commissioner made an agreement with the local Medical Society to pay certain fees—operating on a fee schedule. This agreement went into effect before the TERA scheme started. The question came up in the following year. The mayor and welfare commissioner were concerned because they were not, under the basis of reimbursement established by the Relief Administration, eligible for getting reimbursement on the entire amount of their \$3.00 home visit or \$2.00 office visit. The doctors were united in their stand that they thought it was unreasonable to reduce the amount being paid, since the agreement included provision of free medical and surgical services in the hospital. They claimed that if the welfare commissioner was willing to pay a reasonable amount for services performed in the hospital, they would accept a basis on which the city could get a maximum return from the State. On the other hand, if the city wished to continue on the original agreement, they would be satisfied and would continue to provide free service in the hospital. The welfare commissioner asked for advice as to what the TERA attitude was toward this arrangement. After a study of past expenditures, from an economic point of view, I advised the welfare commissioner to continue on the existing agreement and that it would be more economical for him to pay out of his local funds the difference between the basis of reimbursement established and the locally adopted fee schedule adopted between the welfare commissioner and the doctors.

There is one thing always to be kept in mind in considering this sort of agreement; the welfare commissioner is very much restricted by the appropriations he has to work with. If he hasn't the money he can not extend his policy. If the Medical Society wants a change it should see that the pressure for the change is made on the budget-making authorities, in order that funds be made available to enable the welfare commissioner to be more liberal in extending the scope of his policy.

Question: DR. RAPP: Why should we demand full rates of the welfare commissioner? At the present time we have practically no indigents that we treat for nothing. I am speaking of the situation in Greene County, of course. Why should we expect the full

rate; why not be satisfied with a rate to cover our expenses?

In reply to a question asked by Dr. Bedell, many answered that they are still treating indigents free of charge.

Question: DR. BEDELL: How was the basis of reimbursement of the welfare officer reached?

Answer: DR. DAVIS: This subject has been presented in various discussions we have had in formulating these rules. Basis was variant. I think in the County of Schenectady a certain mass of material was presented to us for consideration with respect to a change, and estimate was made of actual cost of providing care and amount of free care being given.

Question: DR. BEDELL: How much does it cost anyone in this room to make a call?

Answer: DR. CRAVENER: It costs me \$2.33 for every patient that goes through my office. I figured this out last week.

Dr. Davis said he saw no reason why a doctor should be expected to treat patients on an absolutely cost basis when the grocer, etc., are allowed a certain percentage of profit.

Question 13: Has the welfare medical patient the right to choose his physician or specialist in case the welfare officials of the district do not employ specific physicians for this work? If the physician in charge of a welfare patient feels the need of a consultant, what is the proper procedure?

Answer: MR. MACINTYRE: Ordinarily he has that right. In the rural districts, however, it often happens that the indigent patient asks for the services of a doctor who is several miles away. I lately had a case where a sick man asked that his old family physician be called. It happened that this man had formerly lived in a town where this same physician had practiced for many years. The patient had moved some distance to the south of his old home and the physician had moved ten miles north of the town of his original practice. The two were, at the time the man fell sick, about twenty miles apart. In this particular case I could see no reason why I should consent to his calling the doctor whom he wanted. In that case I said "no" and gave him his choice of any one of several reputable physicians who were close by. In the main, however, I do not believe that I have the right to dictate as to what physician should be used. I personally have a choice as to who should be called in case there is sickness in my own family; I feel that the poor person has, within reason, the same right.

I always tell the physician to go ahead and get a consultant if he deems it advisable.

Question 14: What are towns and cities

doing about the fee schedule put out by the TERA; that is, for those cases that are injured while working for the city?

Answer: DR. DAVIS: The fee schedule used by counties and cities can be the locally agreed upon fee schedule and may be used as a basis of reimbursement to the extent permitted under the TERA schedule of "reimbursable charges." There is no absolute fee schedule on hospital charges for persons injured on work relief. Such charges are approved only on an individual basis as to what seems reasonable.

Question 15: Why are the nurses who were employed for an emergency on February 1, 1934 still on duty? Is the TERA or the State Health Department paying them?

Answer: DR. DAVIS: The nurses are still on duty because there are still a great many nurses in need of relief and there are a great many communities in need of additional bedside nursing service. They are paid as a State work relief project by the TERA and the local communities do not share in the payment for their services. The number of nurses on duty depends upon two or three factors; the availability of local supervision, the number of nurses in local community who are out of work and who would otherwise be on the relief lists, and the demand for their services. I can cite one County Medical Society that, before we instituted this service, agreed that it would be most helpful if they could have some kind of service to come in and check on a lot of the false alarms. The president of the County Society said he had been called out several times by people on relief lists to give attention for a heart attack, etc., and when he arrived he would find the woman out hanging out washing or doing some other work. He discovered that the so-called heart attack was merely a passing spell of indigestion. The scheme tried out was to have these nurses on call to make the initial visit and promptly call back for the doctor in cases where there was any indication of his need. No attempt is made by the nurses to make any diagnosis.

Question 16: Why don't more welfare officers seek advice and assistance from the County Medical Society in solving their medical care problems?

Answer: MR. MACINTYRE: I can only answer by saying that in too many cases the members of the County Medical Societies may perhaps not have welcomed the seeking of advice and assistance from welfare officers. I have consulted them and have a mutual understanding with them. I have found them cooperative except in very rare exceptions. You medical men should keep in mind that doctors are the poorest sort of bookkeepers. It is necessary under existing rules and regulations that the county or city welfare official submit a report each month to the TERA in

New York. It often happens that a doctor fails to present his bill until several months have elapsed. Inasmuch as a town welfare officer has to report to the county commissioner once each month, he is placed in an embarrassing position unless he has all of his medical bills for that particular month. The doctors also make the mistake of including bills for different kinds of service on that invoice. To illustrate: I lately had a doctor visit a certain indigent person in his home. His visit to this home was under the Wicks Act reimbursable to the extent of 75% of his charges for the call, which was \$2.00. The doctor immediately called me over the telephone and told me that the patient was suffering from acute appendicitis and must be immediately hospitalized for an operation. The doctor agreed to take the patient to the hospital in his own car. As you know, hospitalization, or any charges connected with it, is not reimbursable under TERA rules. This doctor in rendering his bill included the cost of transportation to the hospital along with his charge for the home call. This necessitated a considerable bit of correspondence between his office and mine and finally it was necessary to send my investigator to visit him in person, that he might render two sets of bills consisting of a single notarized bill for the transportation charges and an original and duplicate bill for the home call.

Question: DR. ELLIOTT: What can a County Society do when it has made repeated approaches to the county welfare commissioner to establish contact and the county welfare officer says he doesn't want any assistance but will arrange things to suit himself?

Answer: MR. MACINTYRE: Isn't there one thing that the men from the rural communities forget? That is that all home relief, no matter what it is, given in a home, in most of the counties in the State is the province of the local town welfare officer; the county commissioner doesn't figure in unless it be an unsettled case.

Question 17: Do the welfare officers realize that, since medical service can be had for the asking, some neurotics are inclined to make themselves a nuisance to the physicians?

Answer: MR. MACINTYRE: Since I have known welfare officers who are practically illiterate, I feel that the large majority of them would fail to know the meaning of the term "neurotics." This is to be expected; they get a very small salary—some of them have been paid the munificent sum of \$25.00 per year. It is not to be expected, therefore, that they should know the meaning of the term referred to above. They are as a rule, however, well acquainted with the people in their neighborhood and know the chronic cases better than anyone else. The physicians in my district also know that class of persons "who enjoy poor health."

Question: DR. RICHARDS: On page 39 of the Manual, where reference is made to the price of glasses, I want to ask Mr. MacIntyre how a public welfare officer is going to get frames provided at the prices listed?

Answer: MR. MACINTYRE: I don't think glasses can be furnished for the prices stated in the Manual.

Question: DR. BEDELL: This question has been brought to our office and I wish that someone who decided this fee could give me a little information. * * *

Answer: DR. DAVIS: The basis for reimbursement was adopted by the TERA and was based on figures received from several of the larger welfare districts upon the actual bid prices being paid by welfare commissioners by agreements with oculist supply houses. The list does not include charge for examination. See the Manual, Regulation 8, Item 3, f, pages 28 and 29.

Question: DR. BEDELL: Are the glasses obtained from opticians or from doctors?

Answer: DR. DAVIS: From the doctor only. One thing to remember is that the TERA has only recently included special medical supplies of this sort as eligible for reimbursement. It is very difficult to get basis for special services. This adopted list of reimbursable charges, I want to emphasize, is the basis on which the State will participate. These charges were previously paid by local welfare departments out of local funds. There is nothing to prevent that from continuing; the welfare commissioner continues to be responsible for necessary medical care. The TERA reimbursement basis is just a way of helping out from State funds.

Question: DR. MACK: Syracuse operates under district physician plan. Not infrequently we are called to attend an indigent patient who gives history of having called city physician the night before. * * * How has the cost of medical care been influenced and in what way in those cities in which the city charter has been changed and the district physician replaced by the family doctor? Also has the change resulted in more satisfactory care of the patient?

Answer: MR. FORD: The city charter will only need to be changed in those cities in which there is provision requiring it. If the city charter does not require it, then no such change is necessary.

Answer: DR. DAVIS: In those cities where charters have been changed the cost has not appreciably increased. Have much more adequate care and the doctors and patients are much better satisfied.

Question: DR. BRENNAN: If the doctors of a city would get together and refuse to do this work at those set fees, would it be possible for the State to send in a city physician to do the work?

Answer: DR. DAVIS: It is entirely up to the local welfare commissioner; he can do it.

Question: DR. POBVIN: I would like to refer to the question asked by Dr. Elliott. Practically all these medical questions are left to the decision of the local administrator. What, if anything, has been done or could have been done in order that the representatives of organized medicine could participate in, or act in some advisory capacity in the decision of these questions? For instance, in New York City we have a director of medical relief. In a recent conversation with me he said: "I try to make arrangements for medical care of home relief satisfactory to the patient and to the physician. However, I must then present this plan to a board composed entirely of lay people. These members are well meaning, no doubt, but they do not possess the medical mind or attitude toward such problems." This is not the fault of the Medical Societies, since we have devoted much attention to these questions, but thus far we have received little consideration from those administering in the Public Welfare Department; for example, a ruling was recently made that the patient on home relief could not select his own family doctor. So many complaints were made about this that the whole plan of having the patient call for the doctor of his choice was reintroduced. We are told that project doctors—the same as those used for CWA work—are being considered. We have asked for a hearing of this matter and an opportunity to discuss the situation and submit methods for the correction of these abuses. So far this has not been granted. We would like to know how to bring about such a procedure.

Question: DR. ELLIOTT: In making contact with the medical profession do you choose or hand-pick from the membership of the Society those with whom you desire to consult or do you go to the elected or constituted heads of the State and County Societies for contact? What is done when no local fee schedule exists? In making up your schedules, do you go back to bills that have been paid and by selection of minimum bills arrive at a schedule?

Answer: DR. RAPP: In our county we simply, at a regular County Society meeting, invited our welfare commissioner to be present and then took up these questions with him. Satisfactory in our county; no complaints. As yet we haven't been able to persuade him that he should pay for indigents in the hospital or obstetrical cases in the hospital.

Question 18: Is a welfare hospital entitled to charge fees and take in private patients?

Answer: MR. FORD: In reference to hospitals connected with county homes, our opinion has been that they are not authorized under the Welfare Law to function as hos-

pitals, but only as a part of the county home. Therefore, any provisions of law which apply to infirmary sections of county homes would be those that apply to all county homes. I know of no provision under which paying patients may be received in a county home. Public hospitals established under the General Municipal Law are authorized by this law to receive paying patients.

Question: DR. BEAMIS: The TERA was to be just a temporary arrangement. Is the object now to make it permanent and further extend medical practice by government agencies on the basis of subsidy from public funds? Who is going to pay for this elaborate program?

Answer: MR. FORD: Answering the first part of the question of Dr. Beamis, as to permanency: The Governor has authorized a commission to study the future of welfare work in New York State.

Question: DR. PODVIN: Is there a medical man on this board?

Answer: DR. DAVIS: I do not have the complete personnel of the board.

At the end of the morning session Dr. Mack moved that a vote of thanks be extended to Dr. Davis, Mr. Ford and Mr. MacIntyre. This motion was enthusiastically seconded and unanimously adopted.

After luncheon Dr. Davis described, informally, the administration of health insurance in Great Britain, as he had viewed it during the summer just past.

Dr. Irving informed the Secretaries that there will be space in the JOURNAL for articles other than those which had been presented at the Annual Meeting and which will be read at coming District Branch meetings. He also asked that all material pertaining to the County Societies or their members be sent to him.

DR. PODVIN: Does Dr. Irving think it would be worth while to devote some space to a discussion of economic problems occasionally?

DR. IRVING: We attempted to start this under "General Correspondence," but did not get very far. If it is not done this way it might look as if the JOURNAL endorsed the opinions expressed in these articles. We shall be very glad to have letters pertaining to the subject.

Dr. Garen suggested the following resolution which was unanimously adopted:

"That the conference of County Secretaries respectfully suggest to the Executive Committee that some provision be made for the formal official contact with the Temporary Emergency Relief Administration to the end of taking part in the discussion of problems that come before that organization."

DR. DOUGHERTY: Refer this to the Committee on Economics. Write me to that effect and I will be glad to take care of it.

General discussion then took place under different headings as indicated below:

Further report by secretary of the Monroe County Society on dispensary problem in Rochester.

DR. MACVAY: I have nothing further to add beyond what has been published in our bulletins, except that all of those interested in the plan think it is working very satisfactorily. Feel we are doing good work in keeping as many people in hands of the private practitioner as we possibly can.

Means of closer and more continuous working relationship between the State Society and the County Societies.

DR. PODVIN: There is one department in which we are very much interested and that is the Legislative Bureau. We should like to know the attitude of our local legislators on our medical problems. In our county we have eight Assemblymen and three Senators. We should like to know how they vote on our bills.

DR. BRILLINGER: I would like to get office to give us information as to what the State Society is doing. Economic questions just as important as legislative. How many men read the information in the JOURNAL?

DR. ELLIOTT: We are depending upon our own initiative in the construction of our mailing list. * * * On at least three different occasions we have requested a list of official personnel of each County Society. Our committee will make it a point to inform the secretaries the first of each month what we are trying to do.

More definite plans for relations of the medical profession with the public.

DR. LAWRENCE: Dr. Sadlier has asked me to express his regrets at not being able to be present, owing to a very sick patient living fifty miles from Poughkeepsie. I think our County Public Relations Committees are beginning to find their place; they are working. I should like to hear from the secretaries whether their committees are active.

DR. RAPP: After about two years our chairman is fairly active. Think he is impressed with the importance of the work and I know that until last winter there were about three physicians who had a habit of advertising everything they did in their offices in the newspapers. Drew up resolutions which the Society adopted unanimously forbidding any names to be given to the newspapers in connection with any professional services rendered a patient.

Postgraduate instruction.

DR. LAWRENCE: Dr. Farmer telephoned

me this morning and expressed regrets at not being able to attend today's conference.

DR. MACVAY: We have a very active Public Health Committee in Monroe County and they brought up the question last year that we are all the time talking about educating the public and said, "Why not educate the practitioner?" The committee has tried to outline a year-round program of postgraduate instruction for the physician—I think with a fair measure of success; but we are not able to get to the people who most need the postgraduate instruction.

HOSPITAL INSURANCE

DR. ELLIOTT: We are urging a complete divorce of the economics of hospital care from that of medical care. Hospitalization costs are such a very precise calculation. Further, in any insured group it is a reasonably accurate factor that one in every fifteen will require hospital care each year. Hospitalization, therefore, becomes an insurable factor. If we permit hospital insurance to include the practice of medicine, in the matter of pathology, x-ray, physical therapy, anesthesia and other specialized forms of medical care, we permit the establishment of a wedge for socialized medicine. There is no point where the line can be drawn in a division of the practice of medicine between these specialties and other lines of activity. In the United Hospital Fund Insurance set up in the metropolitan district, before the enabling law was passed, there was an agreement that they would not include medical care. In every locality the profession must be lured to oppose any institutional encroachment upon the field of medical practice. Under this head I would direct your attention to one practice in the Brattleboro insurance scheme; namely, that of requiring the insured to pay an initial part of hospital care. This acts as a deterrent against malingering and the hospitalization of any inconsequential ailments.

The Public Health Law places the responsi-

bility for the provision of treatment for venereal diseases upon the local health departments. In the case of the indigent, does this health department responsibility include the care of all phases of the treatment of all types and stages of venereal diseases; e. g., the care of pus tubes and the provision of surgical treatment, if necessary, including the payment of the hospital charges, etc.; also the care of old syphilis, such as cardias and aortic cases where the actual administration of anti-leucic agents is secondary and general medical care is primary? Where are the boundaries?

DR. LAWRENCE: It is the Health Department that definitely must pay for treatment of venereal disease cases. However, according to the law, they are supposed to take care only of cases in the communicable stage; but when is a man, or a woman, not in a communicable stage? * * *

DR. GAREN: I asked this question and received an answer from the State Department of Health. The director of venereal diseases said that the local health department is obliged by law to provide treatment for all phases of venereal disease, no stipulation being made with regard to their communicability, and indigency by no means stressed. It is possible for a well-to-do person to demand treatment and get it.

Number of malpractice cases that have been indirectly started by doctors talking too much or trying to tell how much they know to the family of another doctor whom they may see in the absence of the regular doctor.

DR. LAWRENCE: A good many of our malpractice cases originate in that sort of way. I think this is something that the County Societies might well consider to see if they could devise a way of keeping doctors from talking too much.

Dr. Irving referred to two editorials that had been recently published in the JOURNAL on this question.

TO LET THE DOCTORS HALT CRIME

The courts and lawyers have failed, now let the doctors do it. That is the remedy brought forward by Mr. Roland C. Sheldon, Executive Secretary of the Big Brother and Big Sister Federation, in a recent address before the Yonkers Kiwanis Club, as reported in the *Yonkers Herald-Statesman*, and quoted in the *Westchester Bulletin*.

The "mushroom growth" of crime in this country was attributed largely to the neglect of the problem child. Reminding his audience that the annual crime bill in the United States amounts to four billion dollars merely for the apprehension, trial, and incarceration of prisoners and that the total cost of crime in one year amounts to fourteen billions of dollars, Mr. Sheldon asserted that prisons, no matter how modern and strong they may be, are "absolutely futile" in solving or reducing the crime problem.

Studies of problem children have revealed that there are as many as 83 causes for their condition which, according to Mr. Sheldon, "are bases later for incorrigibility and even criminality. Methods that have helped rescue the problem child in other cities and towns," he said, "are playground activities, municipal recreation projects, the elimination of slums, and general betterment of community health."

"The treatment of the problem child must also be individualized," Mr. Sheldon stated. "A program dealing with the children personally must be worked out carefully if there is to be any appreciable reduction in juvenile delinquency."

From the medical standpoint this implies the continuous use of the family physician, with consultants when necessary, and it opens up a whole new field of responsibility for the practicing physician.

Medicolegal

LORENZ J. BROSNAN, ESQ.

Counsel, Medical Society of the State of New York

Charitable Hospitals — Liability for Suicide of Patient

A case decided a few weeks ago by one of the Appellate Courts of this State well illustrates the application of the rule exempting a charitable hospital from liability for the negligence of its doctors. The facts in the case must be detailed at some length for appreciation of the ruling of the court.

A certain M. had manifested peculiarities that had caused his family to become alarmed and he was examined with respect to his mental condition, and it was found he was suffering from involutional melancholia.

Arrangements were made with the B. Hospital for mental diseases, a charitable corporation, whereby he was admitted as a patient upon signing of an agreement that the sum of \$65.00 per week should be paid for his care. Upon his admission to the institution a history was taken which included indications of suicidal tendencies.

Upon the admission of M. to B. Hospital he was put in a private room in the Treatment Hall and at first kept under close observation by a special nurse. Somewhat later his condition had improved and he shared a nurse with some other patients. Still later special observation of M. was discontinued and he was put under ordinary supervision, treatment, and care.

After he had been a patient in the institution for about three months the doctors associated with the medical staff of the hospital considered that M.'s condition had so improved that he would be benefited by putting him in a more active group of patients. At this time a note was made in his record that the doctors in charge of his case felt that he no longer had any suicidal tendencies and he was transferred from what was known as a "Treatment Hall" to a "Convalescent Hall" where patients were given considerable freedom. The doctor in charge in the convalescent hall had issued instructions that the patients in that hall should be taken walking about the hospital grounds in the morning; in the afternoon they should be taken on a walk away from the hospital grounds, all of which was for the purpose of treatment. He had further issued instructions

that the physicians in immediate charge of the patients in the convalescent hall should daily determine whether the mental or physical condition of the patients properly permitted them to be allowed the freedom of the convalescent hall privileges. The physician in charge was in a position at any time to direct special treatments which might be desirable and to prohibit a patient from being allowed to leave the grounds of the hospital.

It was the custom of the institution that when convalescent patients were permitted to take walks outside the hospital grounds they were to be accompanied by what were called "physical aides." Said physical aides were not orderlies or attendants, but they were extensively trained at the institution before they were permitted to undertake their duties of taking out the patients for exercise, and to have charge of them in the gymnasium. It was a rule of the institution that no more than seven patients were allowed to go outside the hospital ground accompanied by a single physical aide.

On a certain afternoon two days after M. had been transferred to the convalescent hall he was taken for such a walk outside the hospital grounds. Various physicians had observed his condition earlier that day and apparently he was in no way abnormal and seemed to be in excellent spirits. Two groups of patients, one consisting of six and the other consisting of M. and four others, each group accompanied by their aides, proceeded for a walk along a public highway near the hospital. The highway was not particularly congested with traffic at the time. A bus, which was traveling along the road at the time, stopped to discharge passengers some 50 or 60 yards from the patients walking along the road. When the bus started up again, and was traveling at a speed of about eight miles an hour, without any warning M., who had been walking along at the head of the group, suddenly got down on his hands and knees and pushed his head under the wheels of the bus, causing his death.

An administrator was appointed who brought an action in the Supreme Court to recover damages for the alleged wrongful death of M. The complaint in the case was based upon two theories: (1) that the defendant had breached its special contract that the deceased would be watched over, cared for, and observed carefully at all times, and (2) that the B Hospital had been negligent in sending the deceased, in company with other patients, in charge of but one physical aide, for a walk upon the public highway. The defendant denied the charges of the complaint and set up a separate defense that it was a charitable and beneficent corporation and that the deceased was a beneficiary thereof. The case came on for trial and at the conclusion of all the testimony the two causes of action were submitted to the jury for consideration. The jury found that there had been no breach of special contract which the plaintiff alleged, but found that the defendant's hospital had been negligent in the case and that such negligence was the proximate cause of the decedent's death. The jury awarded a substantial verdict in favor of the plaintiff as the amount of the pecuniary loss sustained by the next-of-kin of the deceased. The trial judge refused to change the findings of the jury and an appeal was taken to the Appellate Division.

Upon the appeal one of the chief points of controversy was whether sending the deceased on the walk was a medical or administrative act on the part of the hospital, it being the contention of the plaintiff-respondent that the negligence complained of was an administrative neglect for which the hospital would be responsible regardless of the rule exempting charitable hospitals from liability. The court summarized the law dealing with the extent of liability of a charitable hospital as follows:

"The law seems to be settled in this state that a charitable corporation is not liable to patients for the negligence of its doctors, nurses and physical aides in the treatment of those patients, even though a patient paid for the care and treatment which was furnished him."

Counsel for the plaintiff sought to avoid the application of this principal of law by contending that the act which formed the subject matter of the lawsuit was not the negligent act of any doctor or nurse, but was an administrative act of the hos-

pital, for which the hospital would not be immune under the charitable rule. In answering this contention the Appellate Court pointed out that there was no case in this state which directly drew a distinction between administrative and medical acts of the kind presented by the record before the court. It held, however, that it was not necessary to decide whether a charitable hospital would be responsible for an administrative act in this case, since the court found that the act in question was a medical act, and hence immunity furnished to charitable hospitals in the principle of law above enunciated would be applicable in the instant case.

In applying the law to the facts of the case the court said in part:

"I am unable to see in what was done for the deceased in the instant case, anything other than what the records shows to have been proper medical treatment. If we could think of taking patients out for a walk as something quite impersonal, like the exercising of a horse, the act well might be considered administrative; but, accepting what the record shows, that nervous breakdowns with suicidal tendencies on the part of the victim are due to or bring about a loss of confidence and the courage to face one's problems, and promote the desire to find the easiest way out, through death, we can understand that the restoration of confidence and courage is the *sine qua non* to recovery and must of necessity entail risks or leave the case hopeless. The record does not show that restoration of confidence and cure could be brought about if the patient believed himself always under strict supervision. Perhaps nothing would be more depressing to him than a man at his elbow every moment. The record makes it clear to my mind that when a patient afflicted as was deceased is convalescing, little by little, more and more responsibility and liberty of action must be accorded him to help him regain confidence in himself. The hospital should not be held a guarantor. If it succeeds it means life, if it fails, the life remaining is without value. The evidence makes all this clear."

"On the part of the doctors there was an error of medical judgment, deceased was not as convalescent as it was thought, and due to his sad affliction, he succeeded in doing away with himself. No liability should attend his death."

Books

BOOKS RECEIVED

[Acknowledgment of all books received will be made in this column and this will be deemed by us a full equivalent to those sending them. A selection from this column will be made for review, as dictated by their merits, or in the interests of our readers.]

A Textbook of Gynecology.—By Arthur H. Curtis, M.D. Second Edition. Octavo of 493 pages, illustrated. Philadelphia, W. B. Saunders Company, 1934. Cloth, \$6.00.

Conception Period of Women.—By Dr. Kyusaku Ogino. English Translation by Dr. Yonez Miyagawa. 12mo. of 94 pages. Harrisburg, Pa., Medical Arts Publishing Company, [c.1934]. Fabrikoid, \$1.00.

The Dangerous Age in Men.—A Treatise on the Prostate Gland. By Chester T. Stone, M.D. 12mo. of 105 pages. New York, The Macmillan Company, 1934. Cloth, \$1.75.

Postures and Practices During Labor Among Primitive Peoples.—By Julius Jarcho, M.D. Octavo of 175 pages, illustrated. New York, Paul B. Hoeber, Inc., 1934. Cloth, \$3.50.

The Power to Love.—By Edwin W. Hirsch, M.D. Octavo of 363 pages, illustrated. New York, Alfred A. Knopf, 1934. Cloth, \$4.00.

Essentials of Infant Feeding and Paediatric Practice.—By Henry P. Wright, M.D. Octavo of 212 pages. New York, Oxford University Press, 1934.

Surgical Clinics of North America.—Vol. 14, No. 4. August, 1934 (Chicago Number). Published every other month by the W. B. Saunders Company, Philadelphia and London. Per Clinic Year (6 issues) Cloth, \$16.00; Paper, \$12.00.

International Clinics.—A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles on Treatment, Medicine, Surgery, etc. Vol. 3, 44th Series, 1934. Louis Hamman, M.D., Editor. Octavo of 327 pages, illustrated. Philadelphia, J. B. Lippincott Company [c.1934]. Cloth, \$3.00.

Bronchoscopy, Esophagoscopy and Gastroscopy.—A Manual of Endoscopy and Laryngeal Surgery. By Chevalier Jackson, M.D., and Chevalier L. Jackson, M.D. Third Edition. Octavo of 485 pages, illustrated. Philadelphia, W. B. Saunders Company, 1934.

External Diseases of the Eye.—By Donald T. Atkinson, M.D. Octavo of 704 pages, illustrated. Philadelphia, Lea & Febiger, 1934. Cloth, \$7.50.

Chapter I reviews some very interesting historical points.

In Chapter II one discovers the heading "Anatomy of the Eyelids", but the whole matter being reviewed in two pages one feels ill prepared to embark on a detailed study of diseases of the eyelids to which that chapter is primarily devoted. We are disappointed in both the medical and surgical treatment of the chalazion, about which much can be said and done that the author has not touched upon.

The reviewer was dissatisfied with the superficial description of diseases of the lid margins. Certainly this region is worthy of more elaborate attention than is found in the paragraph on Blepharitis Marginalis.

The treatment of a hematoma with lead and opium wash is not quite in keeping with the modern attitude and the reviewer would suggest that the author include the use of iron salts in the treatment of ivy poisoning.

Under "Examination of the Lacrimal Apparatus", the reviewer feels that Schoenberg's "rod palpation" should be referred to in examination of the lacrimal gland.

Lest the reader think that there is no merit in the work, it must be pointed out that the section on "Surgery of the Eyelids" is worth the "price of admission". Moreover, the short snappy sections on rare skin lesions, tumors, etc., are extremely helpful. The good things one can say about this fine work certainly outweigh the minor faults referred to.

JOHN N. EVANS

Chronic Nasal Sinusitis and Its Relation to General Medicine.—By Patrick Watson-Williams. Second Edition. Octavo of 262 pages, illustrated. Baltimore, William Wood & Company, 1933. Cloth, \$5.00.

The author ranks high in his specialty; the book bears a preface by Humphrey Rolleston; and it is now in its second edition. But as we carefully examine the material in the light of a recently changing attitude as regards focal infection we are bound to

feel critical of some of the teachings. The sinus is as potential a focus of infection as the tonsil, in the opinion of the author. For that reason indiscriminate operations on borderline cases would seem justifiable. "Cures" are promised in psychoses and in chronic rheumatoid conditions through operations on the sinuses. The radical practices of the late Dr. Cotton are heartily supported through generous quotations. That isolated cases may respond favorably in spite of operation does not justify wholesale cutting. Then again, that a germ may be cultured from a sinus does not speak for decisive infection; it may also point to contamination. One may doubt the wisdom of devitalizing tissue in the absence of definite proof to warrant interference. In adopting such an adverse attitude as regards the author's contentions, the reviewer is heartily in accord with Barker and other conservative workers.

Had the author confined himself to his specialized field, as in the second half of the book, instead of finding reasons for operating on sinuses in "borderline" cases, it would have registered a much more sympathetic response.

EMANUEL KRIMSKY

Recent Advances in Endocrinology.—By A. T. Cameron. Octavo of 365 pages, illustrated. Philadelphia, P. Blakiston's Son & Company, 1934. Cloth, \$3.50.

This addition to the "Recent Advances" series summarizes in a satisfactory way the status of endocrinology at the present time. The book is a comprehensive compilation of the literature on the thyroid, parathyroid, pituitary, pancreas, adrenals, and gonads with numerous comments by the author who is a biochemist.

The research and investigative work on the endocrines are very adequately covered but unfortunately the clinical application is not as completely discussed. The book will be found valuable by the experienced student of endocrinology as an authoritative compilation of endocrine research but is not of much assistance to the general practitioner from a practical viewpoint.

MURRAY B. GORDON

Papers of Charles V. Chapin, M.D.—A Review of Public Health Realities. Selected by Frederic P. Gormham, Sc.D. Edited by Clarence L. Scamman, M.D. Octavo of 244 pages. New York, The Commonwealth Fund. Cloth, \$1.50.

Recent Advances in Ophthalmology.—By Sir Stewart Duke-Elder, M.D. Third Edition. Octavo of 434 pages, illustrated. Philadelphia, P. Blakiston's Son & Company, Inc., 1934. Cloth, \$4.00.

Experimental Physiology.—By Sir Edward Sharpey-Shafer, F.R.S. Fifth Edition. Octavo of 168 pages, illustrated. New York, Longmans-Green & Company, 1934. Cloth, \$2.20.

The Autonomic Nervous System.—By Albert Kuntz, M.D. Second Edition. Octavo of 697 pages, illustrated. Philadelphia, Lea & Febiger, 1934. Cloth, \$7.50.

A Text-Book of Pathology.—Edited by E. T. Bell, M.D. Second Edition. Octavo of 767 pages, illustrated. Philadelphia, Lea & Febiger, 1934. Cloth, \$8.50.

A Text-Book of Pathology.—An Introduction to Medicine. By William Boyd, M.D. Second Edition. Octavo of 1047 pages, illustrated. Philadelphia, Lea & Febiger, 1934. Cloth, \$10.00.

Influenza.—By David Thomson & Robert Thomson. Quarto of 916 pages. Baltimore, Williams & Wilkins, 1934. (Volume X, May, 1934 of the Annals of the Pickett-Thomson Research Laboratory. Monograph XVI, Part. II.) Paper, \$17.50.

Human Sterility.—Causation, Diagnosis, and Treatment. A Practical Manual of Clinical Procedure. By Samuel R. Meaker, M.D. Octavo of 276 pages, illustrated. Baltimore, The Williams and Wilkins Company, 1934. Cloth, \$4.00.

Modern Treatment in General Practice.—Edited by Cecil P. G. Wakeley, D.Sc., F.R.C.S. Octavo of 426 pages, illustrated. Baltimore, William Wood & Company, 1934. Cloth, \$4.00.

A DISTRICT BRANCH MEETING ADDRESS

ARTHUR J. BFDLLL, M.D.

Albany

[When the President of the State Society visits the District Branches, he explains one or more phases of State activities. The following article is a summary of some of his remarks made at the meeting of the 2nd, 4th, and 7th Districts.—Ed.]

One of the functions of the President of your State Society is to keep you informed regarding the changes that are proposed in the methods of practice and the position your Society takes regarding them.

STATL. MEDICINE PROPAGANDA

There are many paid agents who go through the country sowing seeds of personal antagonism to organized medicine. Some are so clever in phrasing their expressions that they beguile the unwary and attract to their untried schemes many who believe them. It is not uncommon for these destroyers to openly state that they never have any fault to find with the present system of medicine, that it is unfortunate there is so much dissension in the ranks of organized medicine, and that we must consider the layman's point of view in the practice of medicine. If anyone raises his voice in opposition to their theories he is immediately regarded as an obstructionist, one incapable of appreciating life, and is accused of advancing ignorant opposition to change. Now I wish you particularly to note that there is such a thing as opposition to ignorant change. Almost invariably such propagandists exaggerate the hoped for results of their systems and belittle the efforts of thousands of consecrated physicians who have worked unceasingly and often without remuneration for the preservation of general health.

You are told that organized medicine was unprepared for the emergency that was forced upon it in the last few years of economic disruption. You might listen to such arguments and be convinced of their sincerity if medicine was in such a deplorable state, and I assure you it is not as badly off as many other professions. Even

our detractors admit that medicine is not the only division of society which to their minds is in a chaotic state.

I am, and I trust you are, quite satiated with the arguments that are advanced for a plan of medical service which says the physician is to be given his proper place in the sun, and then new schemes are thrust upon him to take from him his right to practice, and I refer in this connection particularly to the statements that the State Health Department wants you the practicing physician to carry on and then in the face of that announcement builds and subsidizes new clinics to compete with you and attract the patients whom you are prepared to protect and care.

I cannot see how it is possible for anyone to harmonize these facts. We are living in a strange age when those whose livelihood depends upon the physician hold him up to ridicule.

The State and local Boards of Health are only our agents and must not attempt to become dictators, for you and I as taxpayers support them.

Isn't it time that the logical body, organized medicine, be given its proper place as the Master in the House of Medicine? Because we have performed our kindly beneficent work without the flare of trumpets and clashing of cymbals, does it lessen its value or does it really reflect our genuine desire to prevent and cure illness?

Too many laymen receive their wages from outside medical agencies. We as physicians must take a stand against any more smooth, mystical word combinations. Those opposed to logical progress in medicine will say that I do not represent the majority of those who are in practice. Ask them for proof. Continue to ask for con-

firmation of their statements which are almost invariably spread by press and air as though the result of serious thought and study instead of being a reflection of their propensity to sit in the spotlight.

The National and State governments are at this time attempting to foist upon you, the practicing physicians of America, untried methods which, however, embody features that have previously failed when put in operation. It is said that organized medicine advances nothing in the way of constructive criticism. A ten-year-old school boy could make a phrase just as forcible and just as senseless.

PLAN FOR ANY NEW MEDICAL SERVICE

At the last meeting of the American Medical Association, the House of Delegates accepted the report of the Committee headed by Dr. Nathan B. Van Etten of New York. I trust that all of you have read it. It is the pronouncement of the American Medical Association representing one hundred and ten thousand practicing physicians.

First: All features of medical service in any method of medical practice should be under the control of the medical profession. No other body or individual is legally or educationally equipped to exercise such control.

Second: No third party must be permitted to come between the patient and his physician in any medical relation. All responsibility for the character of the medical service must be borne by the profession.

Third: Patients must have absolute freedom to choose a duly qualified doctor of medicine who will serve them from among all those qualified to practice and who are willing to give service.

Fourth: The method of giving the service must retain a permanent, confidential relation between the patient and a 'family physician.' This relation must be the fundamental and dominating feature of any system.

Fifth: All medical phases of all institutions involved in the medical service should be under professional control, it being understood that hospital service and medical service should be considered separately. These institutions are but expansions of the equipment of the physician. He is the only one whom the laws of all nations recognize as competent to use them in the delivery of service. The medical profession alone can determine the adequacy and character of such institutions. Their value depends on their operation according to medical standards.

Sixth: However the cost of medical serv-

ice may be distributed, the immediate cost should be borne by the patient if able to pay at the time the service is rendered.

Seventh: Medical service must have no connection with any cash benefits.

Eighth: Any form of medical service should include within its scope all qualified physicians of the locality covered by its operation who wish to give service under the conditions established.

Ninth: Systems for the relief of low income classes should be limited strictly to those below the 'comfort level' standard of income.

Tenth: There shall be no restrictions on treatment or prescribing not formulated and enforced by the organized medical profession."

The origin of all criticism against the present system of medical practice comes from just two groups, the so-called philanthropic foundations and the State Boards of Health.

The discussions of the health of a community are always befogged by the overshadowing, sometimes obscuring clouds referring to the economic status of the patient. No one ever heard of a poor or a deserving patient being refused proper medical care.

The new set-up proposed by so-called social uplifters embodies the same old misconception of obligation on the part of the physician and lack of appreciation by the laity. In one place the socializers tell us that preventive medicine should be stressed and that the proper one to do this is the trained private physician, while at another time they suggest that he be relegated to the background and that medical service be dispensed in practically the same way that alcohol is to-day.

As an example of what State Medicine would mean, I ask each and every one of you to analyze the benefits that you receive from the Workmen's Compensation Law, those which you got from the C.W.A., and then those that you are receiving under the present Welfare Act.

THE STATE BOARD OF HEALTH FAILS TO COOPERATE

The physicians of some districts have had to endure undeserved criticism because of an unwarranted attack upon their skill. I refer to the scandalous attempt to discredit physicians by sending a letter regarding infant mortality to laymen.

My connection with this started when a letter was received from the State Com-

missioner of Health under the date of June 21, 1934, stating:

"I have recently brought to the attention of the mayors of ten cities and the boards of supervisors of ten counties the fact that their city and county were among the ten in the State which have the highest infant mortality rate, based on the five-year period 1929-1933. Attached is a list of the counties and cities together with the rates. In addition, I have sent to the secretary of the County Medical Society in each of the counties a copy of my letter to the local governing authorities."

This was immediately sent to Dr. Farmer, Chairman of the Committee on Public Health and Medical Education, who stated that on June 20th, he had received a similar letter.

He sent out a form letter to the secretaries of the ten county medical societies asking for information as to what action was being taken by them. As President of the State Society, I asked his Committee to investigate the matter, and to prepare a report for presentation to the Executive Committee at its September meeting.

Phases of investigation which Chairman Farmer suggested were:

1. Are the high infant mortality rates in the ten counties listed due to conditions other than those within the field of medical service or public health work?

2. Are there any suggestions to be made for the improvement of medical service or public health work within the ten counties?

3. Are there any suggestions to be made for the improvement of the Governmental health services in the counties?

4. Emphasis upon the importance of the health agencies conferring with the county medical societies before planning or inaugurating any new public health measures.

The "Statistical Report of Infant Mortality for 1933 in 985 Cities of the United States" published by the American Child Health Association contains the following paragraph:

"The large fluctuations which occur in the infant mortality rates for small cities and which have no interpretative significance have been reduced to a minimum by the policy pursued in this report. However, there are other possibilities for error in the interpretation of these rates. As we have shown, failure to correct the residence may

produce fictitiously high or low rates. But even when this correction is made, one is not justified in using the infant mortality rate as a reliable measure solely of the quality of public health effort in a community. The infant mortality rate is a resultant of a number of causes, such as social and economic status, family customs characteristic of different race and nationality groups, climatic conditions, the amount of modern medical service, as well as the amount and quality of public health effort. For this reason we should be careful in ascribing a change in the infant mortality to the one of these many influences in which our major interest lies, namely, organized preventative medicine and public health."

Now gentlemen do you believe that this was an attempt to cooperate with the physician or one to belittle the medical man?

Don't be too lenient with those who constantly refer to the "bickerings of medical men." It reminds me of many of the smoke screens that fill our daily papers to take the reader's attention from the underlying basic principle of self-preservation and sound government.

You elect your delegates to the House of Delegates of the Medical Society of the State of New York, the legally constituted body to represent you. If our critics would in simple justice state the facts back of their controversies and carry their complaints or suggestions to the legal body, progress would be made and much more harmony result.

PUBLIC HEALTH COUNCIL

Agencies outside of organized medicine have for a long time attempted to dictate how you and I should practice. Consider the membership of the body which promulgates the rules of health for the State of New York and note that organized medicine as such has not a single representative on the board. Surely this does not seem to be an attempt at the proper cooperation between the Department of Health and the Medical Society of the State of New York.

Gentlemen, for the good of your patients protect them from the devastating, devitalizing even lethal effects of politically controlled medical service.

344 STATE STREET

EXPERIMENTAL STUDIES ON RADIATION

FRANCIS CARTER WOOD, M.D.

New York City

The facts about radiation, both from radium and x-ray, which interest radiologists are chiefly the biological aspects. The radiotherapist may use physical methods for measurement, but primarily these are of secondary interest to the changes in the body produced by the absorption of the rays. The roentgenologist cares but little about the biological side, except as defining the limit of the number of successive pictures which he may safely take on a given individual. He is not interested in physics in particular, because he uses unfiltered radiation or lightly filtered radiation for his photographic results, and with the exception of special forms of apparatus, like Bucky grids which apply physical principles to the elimination of scatter, his technic has little more reference to physics than the practitioner who listens to heart sounds with a stethoscope or attempts to elucidate the results of an electrocardiogram. Therapy, on the other hand, demands less physics and more biology, and it is the biological side that will be taken up in this paper.

Crude experiments in biology began very early. Becquerel carried a tube of radium in his vest-pocket to London to demonstrate the interesting qualities of the recently discovered radio-active elements to the Royal Society, and shortly afterward he noticed a skin burn. The early picture takers also had some astonishing, occasionally very painful, biological results. There is the famous case of the gentleman in Chicago who had a picture taken of his head and became permanently bald. My early experiences in 1898 as radiologist to St. Luke's Hospital also include a horrifying denudation of one side of a lady's head in attempting to get a picture of her sinuses. One of the earliest biological experiments, about 1897, was by Exner, of Vienna, who deflected beta rays from some radium and showed that the biological effect of radium radiation was not due to the gamma rays, but to the negatively charged electrons. This was confirmed by Abbe years later, and now, of course, it is a matter of common knowledge since the development of cathode ray tubes.

It was in 1913 that that gifted physicist, William Duane of Harvard, while we were discussing some experimental work which I was beginning with radium, told me that I would find that the damage to a cell would be due entirely to the absorbed energy and that this energy would be derived from electrons set free inside of the cell by the impact of the gamma or x-rays upon the atom. This prophecy has been amply confirmed.

The qualitative study of the effects of radiation of both types began early, about 1900. These consisted in the exposure of tissues, chiefly human, to radiation and the study by histological methods of the microscopic changes produced in the cells. Perhaps the most important earlier piece of work was published in 1918 by Krönig and Friedrich, as a supplement to *Strahlentherapie*, on the physical and biological foundations of radiation therapy. At that time the measurement of x-ray was still in a rather rudimentary state. Although Perrin and Duane had suggested the use of the ionization of a measured prism of air between two plates as the best system for quantitative measurement of x-radiation, no accurate method of measuring radium was then known, nor is there yet a method of comparing by ionization the output from a radium capsule and an x-ray tube. All such determinations are still approximate. Krönig and Friedrich improved the open ionization chamber and made some fairly accurate determinations, while the practitioner was still relying on Saboraud's tablets and Kienböck's dosimeter. The small thimble chambers which were then employed showed errors, due to the fact that they were made of metal and had a marked wave length effect. These pioneer investigators, however, did a great deal of preliminary exploration with water phantoms, produced approximate depth dose curves and studied the effect of various filters and the relation of the size of the portal to dosage. About this same time Prime and myself began the investigation of the lethal effect of gamma rays on tumor tissues. Actually this work was begun in 1913, but the necessity of learning a good many funda-

mentals about the effect of radiation from radium tubes, including the necessity for correction for the tube length, and the immense number of animals which were required in the experimentation, prevented the publication of the results until some years afterward. What we worked at was the question of whether twice as much radium was twice as effective in killing tumor cells, with or without heavy metal filtration. We found that within certain limits, double the dose of radium produced twice the biological effect, and that with decreasingly smaller doses a threshold was reached beyond which no effect occurred. We then attempted to find out whether the effect was influenced by the time of exposure, that is whether a smaller quantity of radium produced the same effect at a longer time as a larger quantity at a shorter time, and we found this to be true, with exposures varying in about 1/8. These tests, however, were made on tumor cells *in vitro*. Now we know that by greatly dividing the dose in the animal or human being the healthy tissues can repair. Thus, to produce a given biological result the times of exposure must be comparable, so that if the exposure is suitably prolonged, instead of 500 r causing an erythema of the skin 1,200 to 1,500 r can be given by diminishing the quantity and prolonging the time. Kromig and Friedrich used frog larvae as their biological object, and they found that with equivalent doses and intensity unfiltered γ -ray gave the same biological effect as γ -ray filtered with one millimeter of copper, in other words, the wave length was an unimportant factor. But other experiments did not confirm this. The differences are probably due to inaccuracies of measurement in the aluminum chamber. Thus they found that gamma rays measured by an aluminum chamber had a much greater biological action than γ -rays filtered through one millimeter of copper. We now know that these results are due to the wave length factor of the chamber. Working with skin erythemas, they found that a 25 per cent difference in dose produced no visible difference in the color. On the other hand, using the same aluminum chamber and a filter of one millimeter of copper or three millimeters of aluminum they found that equal doses of γ -rays had the same effect on a human carcinoma. They finally reached the conclusion, however, that biological action was

independent of the wave length and only dependent on the absorbed energy. From the erythemas they drew the conclusion that with equal total doses the greater intensity gave the most marked reaction, but with differences amounting to not more than 1/5 the activity of the reaction was independent of the intensity. They noted that some human tumors were sensitive and some resistant to radiation. They also found no temperature coefficient for the frogs larvae.

Further advances depend on the improvement in the technique of measurement, and as this technique is available chiefly with γ -ray, most of the modern experimentation has been carried on with this agent rather than with radium, which is unsatisfactory because of the impossibility of exactly reproducing experimental conditions. Using an accurately measured, continuous radiation of γ -ray I finally showed that there is no difference in the biological effect between equal quantities of radiation of about 0.2, 0.4, and 0.6 angstroms and that the type of filter made no difference. This has been challenged, but if it is remembered that (1) the effect of radiation is entirely due to the beta rays, as previously stated, (2) as the differences between the beta rays sent off by the atoms at different wave lengths only vary in speed, (3) as the ionization chamber measures the ionization produced in a column of air and (4) the destructive effect on the cells is due to this ionization, there is no reason why there should be any wave length effect, for it is scarcely possible that the cells will recognize and respond, by any biological change, to electrons of slightly differing speeds. This question has been finally settled by Packard, who used more convenient and susceptible material than animal tumors, the eggs of *Drosophila*. Using radiation wave lengths from about 1.6 angstroms to 0.05 angstroms, and measuring the radiation with the greatest care the effect on the flies' eggs and the roentgen dosage has been found to be parallel. Exposure to radium produces a lethal curve of exactly the same shape as that produced by γ -radiation, and as at 550 kv, which is the highest voltage which was available in Packard's experiments the radiation covers a portion of the gamma ray spectrum, it is probable that no difference in biological action exists between radium and γ -ray. Holthausen has brought additional con-

firmation of this fact, showing that the histological changes in tissues rayed with x-ray and with radium, giving the same amount of radiation over the same time, are exactly alike.

About 1904 much research was begun exposing the eggs of sea-urchins of ascaris, frogs, and various larvae to radiation. Bohn and Perthes did some interesting work in this connection, which was chiefly directed to finding out whether there was a stimulating effect from radiation. An enormous amount of work has been done with a great variety of biological material without definite conclusions. The present belief is that there is no stimulating effect produced by roentgen rays or gamma rays. Nor have the most varied attempts to enhance the action of radiation by the introduction into the tissues of heavy metals or of fluorescent materials produced any effective results. Especially the use of fluorescing substances is based upon a complete misunderstanding of the nature of fluorescence which is a molecular and not an atomic phenomenon.

In 1907 Dominici and Regaud began to study the effects on tissues of the filtration of radium and x-rays and discussed the question as to whether there was not a better selective action on the cells if the radiation was given at a slower rate, or, what was the same thing in this instance, more highly filtered. About this period Bergonié, Tribondeau, Regaud, Lacasagne, and Halberstädter also began to study the conditions of maximum damage to the cell and found that when the cell was dividing, it was much more sensitive to radiation than in the resting phase, and that radiation checked cell division and might wholly inhibit mitosis, but that a few hours later division began again, but was abnormal in type, and usually led to cell degeneration.

The next important step was to study on suitable material the effect of varying the rate of the radiation. For this purpose Regaud selected the ram's testicle as offering a material which was highly sensitive to radiation, contained structures which are in active mitoses, and thus had a superficial resemblance to neoplastic tissue. He found that it was possible to sterilize the testicle completely by single doses of radiation, but that the damage to the skin was excessive. However, by dividing the dose in a suitable manner and by giving radiation on successive days, he found

that it was possible to produce complete sterilization without damage to the skin. These experiments formed the foundation for the clinical studies of Coutard, who, since 1922, has been carrying on a careful study of patients rayed with divided doses. Originally he thought that it was the high filtration which produced the elective effect; recently, however, he has come to the conclusion that while the high filtration of 2 or 3 millimeters of copper, for example, are advantageous in shortening the average wave length of the beam and making it more homogeneous, hence increasing the average depth dose, in the more superficial tumors such high filtration or high voltages are unnecessary and just as good results can be obtained by spaced radiation of a much lower voltage. It is the time factor, then, which is important in permitting the restoration of the healthy tissues in the intervals between exposures, while the neoplasm, being poorly provided with blood vessels, nerves, and other controlling structures, does not regenerate as completely as the normal surrounding tissues. This differential is a necessary condition for the successful treatment of neoplasms. During this time also there were a large number of clinical studies made upon the sensitivity of different types of tumors, and rough gradings began to appear in the textbooks. In the last five years the extension of the morphological groupings of tumors has been very great, and an attempt has been made with some success to correlate morphology with tumor sensitivity, but everyone who has any experience in these matters will grant that the results are not mathematically accurate, and that occasionally marked exceptions occur.

The fundamental work of Regaud, however, was of extraordinary importance in changing the whole attitude toward radiation and lead to the abandonment of the administration of massive x-ray doses at a single sitting, or the use of unfiltered or unsufficiently filtered radium, which produced destruction of the healthy tissues as well as of the tumor cells.

Recently the question of increased voltage has rather dominated the field, despite the publication of Packard's results, which showed that the higher voltages were no more effective on the individual cell than the lower. Since we already possess the equivalent of a million volts in radium—and

radium has not been shown to be any more effective in treatment than γ -ray, with the sole exception that it is possible to apply radium locally and over longer periods without discomfort to the patient—nevertheless, even with radium, not as good results have been obtained in tumors of the upper air passages as Coutard has shown can be obtained with γ ray at a voltage not to exceed 200 kv. It is, therefore, very improbable that there is any great advantage in the high voltages. The expense of tubes and apparatus for generating and using 500,000 or 600,000 volts, the amount of current required, and the spacing and lead necessary for the protection of the staff and the patient, all complicate the situation. The real advantage, of course, is that with high filtration, for example, 2 or 3 millimeters of lead, a very short wave length beam is produced at 600 kv with a depth dose considerably larger than the maximum which can be produced at 200 kv at any filtration and any reasonable skin focus distance. Nevertheless, it is possible to get at 10 cm a 50 per cent depth dose with 200 kv. With 600 kv the increase is only about 25 per cent. Whether the practical benefit of this increased depth dose will in any sense compensate for the increased cost to the patient is a matter for careful clinical study. Obviously this development means the concentration of patients in institutions, for the expense removes the apparatus from the range of the ordinary radiotherapist. Rather the attitude is, among the more conservative workers in the field at the present time, that it

is far better to treat with lower voltages and to attempt to apply the radiation to fit the biological factors of the tumor, not wasting time on those patients whose neoplasms cannot be suitably treated by radiation, but to concentrate on the careful dosage of those types of tumors which we know are susceptible to effective treatment. In the meantime, experimentation can be carried out by those who have high voltage plants to determine whether anything is gained by the substitution of 600,000 for 200,000 volts.

INSTITUTE OF CANCER RESEARCH,
COLUMBIA UNIVERSITY

DISCUSSION

DR DOUGLAS QUICK. It is always refreshing to hear from the laboratory side of cancer investigation. We are fortunate indeed to have such an able research veteran as Dr Francis Carter Wood present the subject. In spite of the many and varied disappointments along the way from this point of attack on the cancer problem the information obtained whether the findings be positive or negative all adds to the sum total of our cancer knowledge. While I cannot agree fully with Dr Wood on the dependability of laboratory animals as test objects for therapeutic agents and irradiation effects, it is nevertheless true that work of the past few years has shed most important light on many phases of the complicated neoplastic process. It would seem that the more recent findings have greater practical bearing than heretofore. Dr Wood has already pointed out a number of instances in which the laboratory findings have been directly applicable to the practical problem of the clinical care of the patient. The biochemical data which are being accumulated give substantial encouragement toward an ultimate fundamental specific therapy. The laboratory investigator is no longer an individual apart. He and the clinician are much closer to-day than at any time before.

NEVER AGAIN' FOR THIS DOCTOR

He felt flattered at first when informed in a nice note that he had been placed on the 'approved' list to examine the employees in Wichita, Kansas, of a great world wide oil company. A little later, as the story is told in the bulletin of his County Medical Society, a worker arrived for examination the doctor brought out the blanks with their long list of questions, and the examination began. The questions seemed endless and three hours were gone before they were all answered. Never mind, the doctor was determined to do a good piece of work, and when it was over he heaved a sigh of satisfaction and admiration of the thoroughness of the company. Not till then did he notice on the blank in small type words "A fee of \$2 will be allowed for this examination." He also noticed a blank space for Remarks' which he promptly filled. Here are his remarks: 'Dear Sirs, I am enclosing completed examination of your employee, Mr So and So. It might interest you to know that the enclosed report of the examination required

more than three hours of my time. For this you state you will allow the munificent fee of \$2.00. Now I have two objections to being on your approved list of examiners. First I feel that the fee you allow is about one fifth of the minimum amount that any doctor can possibly afford to charge for this service. You would not ask your plumber to work for three hours for \$2.00. Even if such a request were made your plumber would decline. You would not find a barber who would work the same length of time for the same remuneration. I am a physician with an education which represents a greater expenditure of money than do the educations of your plumber and your barber. So I think, therefore, that your allowance is too small. Second I cannot accuse myself to the policy you have adopted of dictating to me what I shall charge for my services, particularly when your dictates fall at least 80 per cent short. Will you kindly remove me from your approved list of examiners?

THE IRRITABLE COLON

H. WALDEN RETAN, M.D., F.A.C.P.

Syracuse

Chronic irritable colon is a functional disturbance of the colon resulting in abdominal pain, disturbance of bowel movement and, in most cases, in flatulence.

ETIOLOGY.—It is the universal opinion that the continuous use of cathartics is preëminent in the production of the irritable colon. Bran and whole wheat food in some, raw fruit and vegetables in others, mineral oil and psyllium seed at times, contribute their effect.

Besides medication and food, any influence which tends to accelerate peristalsis will have a corresponding tendency to produce the irritable colon syndrome. Thus, achylia gastrica, in which food is improperly prepared in the stomach for small-bowel digestion, is commonly associated with colon symptoms. Hyperthyroidism, with its associated increased nervous irritability affecting the bowel in some cases sufficiently to produce diarrhea, is almost invariably accompanied by some degree of intestinal disturbance. Allergic reactions, in which diarrhea follows the ingestion of some disturbing protein, will cause this syndrome even though of short duration.

Chronic infections in the gallbladder, appendix, pelvic organs, and foci of infection in teeth, sinuses, and tonsils are mentioned as factors but usually are of secondary significance.

An unstable constitutional make-up is found quite frequently in patients who suffer from irritable colon. Likely to develop neurosis, these people also easily fall into the cathartic habit. My experience coincides with that of Dr. Sarah Jordan,¹ who in a study of 1,000 cases concluded: "(1) There is a group of patients who have gastrointestinal symptoms due to a functional disorder of the colon, caused by specific irritation and not dependent on a centrally neurogenic cause. (2) The irritation is usually due to the use of cathartics and enemas. (3) There is another group of patients with unstable colon who have associated neurogenic symptoms. With treatment and relief of gastro-intestinal conditions the neurotic manifestations improve. (4) A group exists wherein the

relief of the gastro-intestinal tract does not improve the neurosis."

It is correct that an unstable, nervous person presents fertile ground for the development of any functional trouble, but the corollary that all who have functional colon symptoms are unstable or that all irritable colon problems are of psychogenic nature is not borne out by experience.

MECHANISM OF PRODUCTION.—The factor which seems to be common to all causes, direct or indirect, is the acceleration of the passage of food through the intestines. This fact is established by the soft, sour stools which these patients frequently have, by x-ray examination and by what is known about the action of cathartics and the result of their continuous use.

The increased irritability then must first exist in the small bowel and result in incomplete digestion and absorption of food. Thus, excessive amounts of incompletely digested food are swept into the colon. Bacterial action then contributes its part in the production of the irritable colon by the fermentation of the undigested food. This results in the excessive production of gas, acids, and other chemical bodies in various amounts. All these substances are irritating to the colon mucous membrane.

The summation of the irritating action of harsh foods, cathartics, and the products of bacterial metabolism results in a hypersensitive mucous membrane. Inasmuch as this membrane acts as the receptor in the myenteric reflex it is logical to expect a correspondingly increased motor response.

This may produce mass contraction with colicky pains, located in the transverse colon or left or right side of the colon. There may be smaller areas of irritation and less severe pain or only a mild degree of disturbance resulting in only a distress of vague character and of variable degree.

To-day it is generally believed that distention of a hollow organ, the lining of which is irritated or inflamed, results in pain. Ryle² and others have studied the production of visceral pain; he concludes

that pain resulting from increased tension with stretching of the muscle fibres is felt in the organ so affected. Failure of the muscle to relax (spasm) may be painful, too.

Whether colonic pain of a functional cause is referred according to the somatic distribution is beyond the consideration of this discussion. However, many times, on carefully palpating a tightly cramped descending colon, I have had the patient refer the discomfort to other parts of the abdomen.

The location, character, intensity and duration of the pain vary considerably as cases are compared. This is to be expected when one considers the size, location, and distribution of the colon and recognizes all of the factors influencing its function. And while it is not possible to crystallize the diagnostic criteria into a couplet for convenient reference, it is possible to create a clinical picture which can be recognized by careful analysis and examination.

THE CLINICAL PICTURE—The chief complaints are constipation, abdominal distress or pain, and 'gas'. These have endured for months or years and vary in severity, but tend to become more annoying. Cathartics, mineral oil, high roughage diet, or enemas containing soda, soap suds, or other chemicals are being used to correct the constipation. Occasionally, constipation is not a symptom but, on questioning, it is discovered that one or more stools of softer than normal consistency are occurring each day.

The distress may be colicky and be located at or below the navel. It may simulate ulcer discomfort,³ with the customary relationship to meals. The distress may localize in the right lower quadrant and be mistaken for mild appendicitis. Rather frequently the discomfort is centered in the upper abdomen and quite often approaches a picture of chronic cholecystitis. If an acute attack occurs, especially in an older person who is known to have heart disease, the phenomenon may simulate what has been described as abdominal angina.

It is thus obvious that many true pathological conditions are simulated by the irritable colon. It is equally true that this functional syndrome may coexist and serve to mask real disease.

Inasmuch as the distress of irritable colon is largely of mechanical origin, in-

fluences which alter the dynamics of the gastro intestinal tract also alter the distress. Thus, passage of stool, passage of flatus, the change in gas tension which occurs when noises start rumbling through the abdomen and at times change in position, all tend to relieve, though at times only temporarily, the distress of colonic origin. Belching of gas may also reflexly relieve the distress due to colonic spasm.

An important symptom of the irritable colon is what might be called an abdominal desire for bowel evacuation. Normally one feels the defecation desire as a feeling of fullness and pressure in the rectum. If there is a cramp or other manifestation referred to the abdomen, it is reasonably certain that an irritable colon exists. Without suggesting the reply, one should ask where and how the patient feels the urge to empty the bowel. If one is met with a blank expression, or the patient appears not to understand the question, the examiner may ask: Do you feel it in the rectum or through the abdomen? It is usually not difficult to determine whether the reply is reliable or not.

The consistency of the stool in these cases is almost invariably softer than normal. Obviously this may be the result of the means employed to correct the "constipation," but the result—an acid irritating stool—is the same, whatever the means. This feature of the examination demands special attention. Most people do not know what a normal stool is and few are able to give an accurate, reliable description of their stools. A normal stool should be formed, firm and compact, and more or less banana shape and from 1½ to 2 inches in diameter. The color is of little significance in irritable colon. Because of the difficulties in obtaining reliable observations by the patient, it is much better to inspect a specimen of stool, which the patient brings in a glass jar, to the physician. Almost invariably a soft, gruelly, and mushy mass will be seen. Remnants of undigested food, mucus, and gas bubbles, mutely signifying the fermentation occurring in the colon, can be seen directly through the glass container.

Some idea of the degree of fermentation taking place in the colon can be obtained by ascertaining the amount, frequency, and odor of the flatus expelled per rectum. Normally, gas passes without effort at the time of stool or just before. There should be no abdominal discomfort preceding it.

In hypersensitive colon cases there is marked increase in all of the fermentation phenomena. Some patients will recall that the stool passes as an explosive movement, others will mention the obviously large amount of flatus which they are called upon to expel.

Frequently, the first bowel movement occurs before breakfast. This usually means a rather high degree of colon irritability. Occasionally the urge for bowel movement is sufficient to awaken the patient. These details, brought out in a carefully taken history concerning a patient's bowel habit, reveal existence of a colon usually abused by its solicitous host. The abdominal symptoms are resulting not from the constipation which the patient believes exists, but to the treatment which is being used to correct the constipation. Actually, these patients are not constipated. It is quite the rule to find that their peristaltic response to the stimulation of a diet containing an average amount of cellulose fibre of a bland type is greater than normal.

PHYSICAL FINDINGS.—It is of paramount importance to make a careful, painstaking, complete physical examination, although the characteristic physical findings are confined to the abdomen. There is no constant body habitus, no typical constitutional make-up which offers any positive indication that one is dealing with this functional colon derangement. Careful palpation of the abdomen reveals a tender colon. It may be tightly contracted, simulating a firm tube. This observation has resulted in the use of the term "tonic hardening of the colon," by T. Stacey Wilson, of England.

The colon is best felt, employing a rolling type of palpation in the left and right iliac fossae and in the mid-abdomen or just below the navel. The two flexures are not palpable, due to the elevation of the ribs and the deeper position of the colon at these points. The experienced hand soon learns to feel through the abdominal wall and to be insensitive to skin contact. It is actually possible to appreciate the increased tone and thickness of the colon in many of the cases where the abdominal wall is not too thick.

Distention of the abdomen may be a pronounced observation and tympany, naturally keeping in mind the normal location of tympany, may be helpful. One will never see peristaltic waves in this condi-

tion unless the abdominal wall is parchment-like in thickness.

Rectal digital examination reveals nothing characteristic, and proctoscopic studies, as a rule, merely show increase in mucus and some evidence of venous congestion. Conversely, however, an irritated anus or rectum can be the cause of a reflexly irritable colon.

Roentgenologic examination should include the opaque enema and the opaque meal. The enema commonly shows cramping or spasm of the colon. This may be general or rather sharply localized. It is rather common to see the descending colon narrowed throughout its lumen to a pencil thickness. In other cases a good-sized colon will be seen and, as the tension increases, a very rapid cramping occurs beginning perhaps at about the splenic flexure and passing downward forcing before it the colonic content. At times this is sufficiently severe to force the enema back into the container and may be exceedingly painful. I have seen such a mass contraction begin at the hepatic flexure and completely empty the colon distally to this flexure, while the patient complained of abdominal pain which exactly duplicated the distress of the chief complaint. The reproduction of the patient's distress by distention of the colon is a frequent and reliable finding and can be done anywhere. It is not necessary to use the opaque enema on a fluoroscopic table. The findings in the stomach and duodenum are not constant. Some observers⁴ have described an increased irritability, but I have not seen this. My findings are, first, that the meal has usually progressed further than normal in the 5-hour interval between the first two examinations, frequently filling the entire colon; and, second, the haustral markings seen in the colon either at the 5-hour or 24-hour screen examination are deeper than normal. Some very excellent roentgenologists take the position that no characteristic can be described as diagnostic of colonic dysfunction. Perhaps this is due to the fact that their patient preparation includes castor oil and irritating enemas. The cramping which they uniformly see they conclude is physiologic. May it not be the result of the purge? At any event a thorough study of these cases should be made to eliminate as completely as possible the existence of organic surgical lesions, and obviously this can be done best by careful roentgenologic examination.

TREATMENT—All cathartics must be carefully avoided. In place of the laxative stimulation, normal bowel peristalsis is reestablished by supplying an adequate roughage of a bland nature in the diet. Usually, I recommend the avoidance of potato, peas, corn, lima and baked beans, foods which are unusually high in starch and cellulose, and the interdiction of raw vegetables and raw fruit with the exception of citrus fruit juices.

Nuts, honey, marmalade, popcorn, veal and most sausages are not well tolerated. Drinks to be avoided, in all cases, are beer, gin, buttermilk, and malt preparations. In some cases even milk, tea, coffee, and the less irritating spirits are better avoided. Simple desserts, bearing in mind the avoidance of rich sauces and heavy puddings, are allowed. I make it a practice to specify a definite amount of cooked vegetables and fruit⁵ so as to establish an adequate bowel residue. This amount is altered later depending on the character of the stool which results. Cereals and bread, with the exception of those containing whole wheat and bran, are allowed but emphatically the whole grain products cannot be tolerated at all. The leafy or rooty vegetables are usually well borne, especially if thoroughly cooked. Some people find that cabbage, turnips, spinach, and onions are distressing, and when such observations are noted it is best at first to allow the patient to have his way. Cooked fruits, avoiding those with firm seeds, are valuable. They can be obtained everywhere, either as commercial products or as home canned or home cooked fresh fruit. Cooking softens their fibre and lessens their irritating action. People who are not comfortable after eating raw apples can take apple sauce or baked apples without trouble. Beef, lamb, chicken, turkey and fresh fish are usually the meats of choice. These should be well prepared and the fattest part left for others.

By mouth, the drugs of choice are those which directly or indirectly result in quieting bowel cramp. They are belladonna and hyoscyamus, bromides, phenobarbital, and the insoluble heavy alkalis that are not laxative. In the most severe cases opium is helpful in carefully controlled dosage, if used for a short time. External heat applied over the abdomen for 20 minutes especially after eating will be soothing to some. A woolen abdominal band will protect against sudden changes in temperature

and thereby help to prevent a temporary recurrence.

As one watches the progress of the case the opportunity frequently will be found for doing what the physician thinks wise in the way of suggestive therapy. Many times it will be possible to assist the patient to a better understanding of some psychic problem and thereby help him to regain his poise.

Autogenous vaccine occasionally will find a place in the therapy of the most difficult cases.⁶ My results, however, have been somewhat disappointing in its use in functional colon cases.

The fundamental requirement in these cases is to obtain as nearly as possible a normal stool. Such a stool must not be so hard as to irritate the anal canal but firm enough to signify a normal rate of passage of food through the bowel above. It may take weeks or months of careful adherence to a strict regimen of diet, rest and sedatives before the desired result is obtained. Some may never attain the ability to handle with comfort an unlimited diet. Practically everyone, however, can have normal bowel activity established and almost invariably this will bring comfort.

The ingenuity of the physician who manages the hypersensitive colon problem will be taxed at times by the likes and dislikes of the patient. Many times an incorrect conclusion that this or that food is the cause of his distress has resulted in a very limited diet. The mechanism of production of his distress must be explained carefully and the confidence of the patient developed in the rationality of the management outlined. Time must be given to explain what a normal stool is, why it is necessary to obtain such a result and why comfort can be expected when the rate of passage of material through the digestive tract approaches the normal. A cooperative patient then is ready to follow instructions accurately.

For the first few days after discontinuing the cathartics, which means, in some cases breaking a habit of several years' duration, the patient may need some assistance in starting the defecation. This is provided by several means. A retention enema of one or two ounces of olive, mineral or cotton seed oil at night will be helpful in some, others will find a glycerin suppository or a two ounce bulbful of warm saline solution in the morning sufficient to start, what to them seems a rather

miraculous phenomenon, but which, after all, is merely the reestablishment of a normal mechanism.

CONCLUSIONS.—The irritable colon syndrome is defined and its clinical picture and mechanism of production explained. A broad outline of treatment based on what appears to be the essential factor common to all cases—the obtaining and maintaining of a normal stool—is given. Obviously, various individual approaches to the therapy of these cases may be developed. Careful observation will show, I believe, that when relief is obtained, whatever the means, the stool will closely approach what has been described above as the normal stool.

DISCUSSION

Dr. LEWELLYS F. BARKER, *Baltimore, Md.*: The account of this condition given by Dr. Retan seems to me admirable and there is really very little that anyone can add. The condition he describes is mainly functional rather than organic and is relatively common in persons of nervous constitution, especially when they are underweight.

The condition seems to be associated with hypervagotonic states, that is to say, in patients in whom the innervations going through the craniosacral autonomic nervous system overbalance those that go through the sympathetic system to the bowel.

Dr. Retan has mentioned belladonna and atropine for the relief of spasm of the colon. I might add that I have often seen very good effects following the use of novatropine tablets (1 mg.), one after each meal for a time.

In patients who are very run down and nervous a thorough rest and isolation cure, during which the patient is compelled to gain weight by means of a suitable diet and by injections of a few units of insulin half an hour before each of the two principal meals, may sometimes be very helpful.

If all general practitioners would take to heart what Dr. Retan has told us, there would, I feel sure, be fewer failures in medical treatment and far fewer unnecessary operations, for the removal of the appendix or gallbladder in the types of patients he has described.

I am glad that he called attention to the abuse of colonic irrigations for the treatment of this malady. Formerly many physicians prescribed colonic irrigations as almost a routine measure in such cases. I am glad to note that the practice is being abandoned.

LOWEST DEATH RATE ON RECORD

The Bureau of the Census announces that in 1933 in the United States there were 1,342,073 deaths from all causes, representing a mortality of 10.7 per 1,000 estimated population. This is the lowest death rate since the annual collection of mortality statistics was begun in 1900. With the admission of Texas, in 1933, the Bureau is now able for the first time, to publish deaths and death rates complete for the entire population of continental United States.

Of the 18 groups of causes of death into which a table prepared by the Bureau is divided, 11 show decreases in rates as compared with the previous year; 5 show virtually no change, and only one, "diseases of the circulatory system," shows a significant increase. The cause within this group which showed the greatest increase, both in number of deaths and the death rate, is actually, "the coronary arteries." The increased tone and increased rate of the digestive system many of the causes are lower than that for wall is not too thin.

Distention of the "cancers and other pronounced observed during the past usually keeping in mind, the rates were slightly of tympany, may be receding years, 1932 never see peristaltic wa.

Of the decreases in death rates for 1933 those for the following groups are noteworthy: "Infectious and parasitic diseases," "diseases of the respiratory system," and "diseases of the genito-urinary system." The decrease for the first of these groups is largely accounted for by the drop in the number of deaths from influenza and tuberculosis. In the second group the decrease is attributable mainly to the lower rates for the pneumonias. The decrease for the rate in this group is in keeping with the decline during the last few years in the death rate from "chronic nephritis." The decrease in "diseases of pregnancy, childbirth, and the puerperal state" was approximately the same from 1932 to 1933, as from 1931 to 1932, and is due in large number to the lesser number of deaths from puerperal albuminuria and eclampsia, as well as from puerperal septicemia.

Although the rate for "violent and accidental deaths" was slightly lower in 1933 than in 1932, it will be found that within this group the rates for some of the individual causes, notably "homicide" and "automobile accidents," are higher.

Prior to the issuance of this summary, a table of death rates and deaths by principle causes was compiled for each State in the registration area. Copies of these State summaries are available upon request from the Department of Commerce, Bureau of the Census, Washington, D. C.

ECZEMA OF INFANCY AND CHILDHOOD

Neurodermatitis Disseminata (Type II Eczema), Atopy in Eczema

SAMUEL M. PLCK, M.D.

From the Pediatric Service of Dr. Bela Schick, Mount Sinai Hospital and the Department of Dermatology Service of Professor Howard Fox, New York University and Bellevue Hospital Medical School, New York City

Continued observation and study of the eczemas in infancy and childhood by means of patch tests have convinced us that this method of testing for etiologic agents is certainly of great practical value. We still believe that it is much more important than the scratch method.

Unfortunately, because of the complex nature of this disease and because of the number and variety of the etiologic agents, and above all, because of the great difficulty in carrying out thoroughly and expertly all of the tedious diagnostic measures, it is very difficult to finally eliminate all of the necessary factors to bring about a cure in many of the cases. The approach to the whole problem would be made very much easier if, instead of looking for etiologic agents, a method of changing skin reactivity could be devised. Our experience seems to indicate that for the present there is no short-cut to the solution of this problem.

The present report is based on an analysis of ninety three cases of eczema in infancy and childhood.* A number of these have been observed for two or three years. Fifty of the patients were discussed in our first paper,¹ many of whom have been followed to the present time so that much more data on their course have been acquired.

METHODS OF INVESTIGATION

All of the cases were tested by the scratch and patch methods with the list of substances given below. Detailed description of the technic has been given in a previous paper.¹ The list of proteins cited is smaller than those which were actually used in the majority of the cases. It represents a group of test substances which seems to be sufficient for practical use.

Test substances †

Wheat ✓	Orris root ✓
Wheat globulin	Pyrethrum
Wheat protease	Kapok ✓

Wheat leukosin	Cotton seed
Egg white ✓	Silk ✓
Egg yolk	Flaxseed
Lactalbumin	House dust
Goose feathers ✓	Ragweed, short
Chicken feathers	Ragweed, giant
Duck feathers ✓	Timothy
Cheese (American) ✓	Orchard grass
Herring	June grass
Pike	Red oak
Salmon ✓	Brazil nut
Smelts	Red top
Almond	Plantain
Tomato ✓	Horse dander
Sheep wool ✓	Horse serum ✓
Goat hair ✓	Rabbit hair ✓
Cat hair ✓	Cattle hair ✓
Dog hair ✓	

The elimination diets followed were those recommended by Rowe,² Hopkins and Keston,³ and some of our own modifications.

CLASSIFICATION OF ECZEMAS

In our first communication¹ the true eczemas of infancy and childhood were classified into Types I and II with inter-related forms. *Type I* may be either wet or dry. In the dry subgroup there is erythema, which is sharply circumscribed and covered by fine scales. The areas of erythema vary in size and shape, and when they become confluent, cover large areas. In this form there are often lichenification and edema. In the wet type, owing to the exudation, there is often a great deal of crust formation. The scalp, neck, and face, and especially the cheeks are practically always affected. When the condition is found on the extremities it is usually the extensor surfaces which are involved. The chief characteristic and primary lesion of this type of eczema is the formation of vesicles. It is this type which has been called by Czerny, Rost, and Keller⁴ the early period of the exudative diathesis. The basic lesion of *Type II* is a skin-colored papule. The papules have a tendency to grouping and as a result there is the formation of plaque-like lichenified, sharply circumscribed, dry, infiltrated areas. The flexor surfaces of the joints,

* These investigations have been carried out in cooperation with Dr. Gustav Salomon.

† Arlington Proteins were used (Arlington Chemical Company, Yonkers, N. Y.).

especially the elbows and knees, and the sides of the neck are areas of predilection. This is the type which closely resembles *disseminated neurodermatitis* of the adult.

INFANTILE ECZEMA

Twenty-three infants up to one year of age were included in this group. Only 3 patients with a Type II eczema were seen. The significance of this finding will be discussed later.

Thirteen of the cases had positive skin tests. Of these, 9 were positive by patch tests and 10 gave reactions by the scratch tests.

Four of the cases were positive to food proteins by the patch tests; 2 to wheat, 1 to the fish group, and 1 to egg white and egg yolk. It was usual for infants who showed a positive patch test to food proteins to have positive patch tests with inhalants and other substances. It was not until both were removed that an improvement in the eczema was seen.

Eight of the patients had positive patch tests for contact substances. Six of these were positive to the feather group, usually to goose, duck, and chicken feathers, but in some instances only to goose and duck feathers. Goose feathers gave the strongest and most frequent positive test. Of the other 2 cases, one was positive to cattle hair and sheep wool, and one to dog hair.

When the environmental substances which gave the positive patch tests, especially feathers, were removed, there was a definite improvement of the eczema. One of the feather-positive cases has been observed for almost four years and has remained free from eczema for three years after the removal of the feather pillows.

In 3 of the cases there were positive immediate reactions to external substances; one to goose feathers; one to duck feathers (also positive to duck feathers by patch test) and one to orris root, silk, pyrethrum, and *aspergillus niger*.

Nine of the cases showed positive immediate reactions to food proteins, 8 of whom were sensitive by test to egg white and egg yolk. The ninth patient was positive to milk, wheat and radish. Elimination of the addition of eggs to the majority of the positive cases had no effect on the eczema. As has been concluded in the previous paper, the positive scratch test to egg was an index of the eczematous infant or child, but it was nonspecific in so far as the elimination or addition of this protein

had no effect on the course of the eczema in the great majority of the cases.

There was only one case in which the scratch-positive substances seemed to play a rôle in the course of the eczema. The case history follows:

Female, aged 10 months. First seen with Type I eczema on both cheeks. There was a definite history of allergy in the family. The patch tests were negative. Scratch tests with egg white, egg yolk, orris root, silk, pyrethrum, and *aspergillus niger* were positive. This case cleared up completely in the hospital in a very short time. Forty-eight hours after she returned home there was a recurrence. Diet and the elimination of scratch-positive substances was then rigidly observed. For eleven months under this régime she was never quite clear of eczema. It was noted that spinach and oranges increased the eczema. Contact with silk caused exacerbations of the lesions at times only. The eruption then gradually disappeared.

The striking observation in this case was the prompt improvement upon removal from the home, and the recurrence on return. This certainly seems to indicate some environmental contact as an etiologic agent. Since the child was sensitive to *aspergillus niger*, the house dust might have played a rôle. It was very hard to evaluate the rôle of elimination of the scratch-positive foods because of the length of time that it took for the eczema to clear up.

The recurrence after contact with silk was also very difficult to determine definitely because of the unreliability of the flare-up after contact. There is no doubt, however, that diet played a rôle in the eczema.

Hill⁵ in a very careful analysis of a large series of infantile eczemas has come to the conclusion that scratch tests are often of value in infantile eczema. Certainly this has not been substantiated in our material. It is striking to note that just as in our series egg white or egg yolk gave the greatest number of positive immediate reactions in his cases. However, he admits that these positive tests have been of little clinical significance. Since in the smaller series of cases there were very few who showed positive immediate reactions to anything but egg white and egg yolk, the difference in the evaluation of the results might be thus explained.

A very striking example of the clinical significance of the patch and scratch tests was furnished by the following case. It was the only one in the infantile group which was sensitive to one of the feather group by both patch and scratch test.

A 10 months old male developed eczema at two months of age, on the chest and trunk. It was vesicular, papular in type (Type I). The family history was negative for allergy. Patch tests with duck feathers and goose feathers as well as wheat were positive. Scratch tests were positive to duck feathers. There was some improvement when the feathers were removed and a rather rigid diet was maintained but there was a constant tendency to recurrence. While the child was under observation, he developed asthma. Feathers could be shown to have an influence on both his eczema and his asthma. When contact with feathers was definitely removed, the recurrences of both became rarer. This case is a rather striking example of the interpretation of the scratch and patch tests. The patch test to feathers explained his eczema, while the scratch test indicated a type of hypersensitivity resulting in asthma.

Elimination diets were given particular attention in this group. In a number of the cases elimination diets suggested food which seemed to play a rôle. It was striking in that most of the cases were not completely cured by the elimination diets, but that there was definite exacerbation on the addition of offending substances. Milk, wheat, and eggs were the chief offenders.

ECZEMA AFTER INFANCY

Seventy children from one to twelve and one half years were studied. Twenty-five had been previously reported.

Thirteen of the patients were positive to food proteins by the scratch method, while only 3 were positive to inhalants by this method of testing. Only 3 of the cases gave positive patch tests to food proteins, while 18 gave patch tests with contacts (inhalants), of these, 10 showed a positive reaction to the feather group.

Our experience in this group also has led us to conclude that patch tests with substances other than foods were much more reliable than the scratch method in their practical application in determining the cause of the eczema.

Elimination diets proved very unsatisfactory in this age group in influencing the course of the eczema, irrespective of whether they were based on scratch- or patch positive tests or not. Patients positive to food proteins by patch tests were rare and were usually accompanied by patch positive tests to other environmental substances.

NEURODERMATITIS DISSEMINATA (TYPE II)

The eczemas of infancy and childhood have been divided into Types I and II, because the difference clinically has been very

striking. In a previous paper it has been pointed out that those which have been designated as Type II very strongly resembled, clinically, the 'generalized neurodermite' of Brocq, or the "lichen chronicus simplex disseminatus" of Vidal. This is the type which has been named by Rost 'Das spateludative Eczematoid'. This form of eczema is characterized by a skin-colored papule as the basic lesion instead of a vesicle as in Type I, and for its predilection for the flexor surfaces of the joints, especially the elbows and knees.

Sulzberger⁶ and his coworkers have studied a series of cases of adults with neurodermatitis disseminata and they have stressed not only the clinical differences between this group and the contact or vesicular type of eczema (dermatitis), but they have pointed out that there were other characteristics such as a high incidence of atopy, a positive personal history of allergy, and a great number of immediate reactions, rather than patch tests, which were of clinical significance in this group.

It would be important if this point of view could be seen to apply to the eczemas of infancy and childhood (Type II) which resemble adult disseminated neurodermatitis so closely.

Twenty three cases were studied, a number of which have been followed over a period of years.

Age—Of the 23 infants studied only 2 showed this type of skin involvement. Yet, of the 22 cases of neurodermatitis disseminata which we are here reporting, 15 gave a history of infantile eczema.

We were able to follow 5 of the cases from infancy through early childhood. In all instances during their first year they presented a typical Type I with vesicle formation which was located on the face, scalp, or extensor surfaces of the arms. The typical Type II localized to the flexors of the elbows and knees usually developed after the second year.

Only 2 cases have been seen with Type II eczema below one year of age, 3 between one and two years of age, 3 between two and three years of age, and all the rest in children over three years of age.

It was evident that a definite change in the reaction of the skin had occurred in the 5 infants who were seen to change from a Type I to a Type II because the recurrences were always primarily papular once the neurodermatitis disseminata had

developed. Therefore, we were not dealing with a chronic lichenified eczema but actually with a primary neurodermatitis. It was not uncommon in the transition period to see a Type I on the face, and a Type II in the flexors of the joints. We think that we have established by the foregoing statistics that in the majority of the cases a Type I usually precedes a Type II. That this is not necessarily always the case was seen from the fact that we had 4 cases in older children, where the primary onset was characterized by a papular eruption in the flexors of the elbows and knees. It is impossible in infancy to predict from the clinical characteristics which of the infants were likely to develop into a Type II.

History of Allergy.—Twelve of the 23 cases had an allergic family history. Of the 70 cases with vesicular eczema, only 10 gave a similar history. Since some of the younger individuals which were included among these cases might eventually develop into a Type II, the figure is probably even lower.

Personal History of Allergy.—Only 3 of the 22 Type II cases had a personal history of allergy, 2 with asthma and one with hay-fever.

Tests.—Thirteen of our cases gave positive reactions by the patch or scratch method. Only one had reactions with both.

Scratch Tests.—Seven of the cases gave positive immediate reactions by scratch tests. Two gave a reaction to egg white and egg yolk; one to egg white alone; one to mustard and radish; one to the fish group; one to cat hair and feathers and one, with hay-fever, to orchard and June grass.

Patch Tests.—Six of the cases were positive by the patch method; two to goose feathers, chicken feathers and dog hair; one to goose feathers and dog hair; one to flaxseed and egg white; one to wool and one to cattle hair, sheep wool and wheat. It can be seen that just as in our other cases the scratch tests were usually positive for food proteins and the patch tests usually gave reactions with substances other than foods.

Again egg white gave the greatest number of reactions with the scratch tests and animal emanations were most often positive among environmental substances.

Clinical Course.—Hospitalization or removal from home environment was of striking benefit in many of the cases irrespective of the diet regulations, which certainly seems to speak for a contact (inhalant) as an important contributing factor. Quite a number of cases, however, could not be controlled as far as the recurrences were concerned in this way. The prognosis for an eventual cure is definitely worse in this group with any method of therapy, as compared to the children showing the Type I eczema.

The elimination of the scratch-positive substances did not prove of very much value in influencing the clinical course. It is realized that the majority of our immediate reactions were due to food proteins and these were of little value in helping us control the course of our eczemas. Sulzberger⁶ and others stressed the importance of silk as an etiologic factor. In their cases the hypersensitivity was elicited by intradermal testing, the patch tests with silk were negative. Since no intradermal tests were done, we cannot properly evaluate this finding.

Exacerbations were definitely noted in several instances on eating certain foods but no case was seen that was completely cured, although a few seemed to be improved by very rigid diets.

In our group of patients the scratch test with silk was not positive. Although we were dealing on the whole with poor patients it is hard to conceive that contact with silk was entirely avoided. In this respect, of course, it is important to bear in mind that contact is necessary before an eczema or a sensitivity develops to one of the environmental substances. L. W. Hill⁷ tested a number of infants with feathers and was unable to get any positive tests. However, out of the group of 25 infants tested, only .5 slept on feather pillows. In our series all of our feather patch-positive cases slept on feather pillows, either in the bed or in the carriage.

The child sensitive by scratch test to cat hair and feathers improved while in the country. But at home there was a prompt recurrence, even though both of these substances were supposed to be eliminated. Just as in our previous experience with infants, the sensitivity to egg white seemed to be a stigma of an allergic individual rather than a specific indication of an etiologic factor. In only one case with the positive scratch test to egg white in

our series did we get exacerbations of the eczema on eating eggs.

Our results with patch tests in this group have not been nearly so striking as in the Type I. While an improvement was noted in a number of cases when patch-positive substances were removed, especially those sensitive to wool and feathers, the majority of cases with positive tests were not completely cured. This might have been due to the fact that by our method of testing only a few of the allergens which played a rôle were entirely eliminated. Certainly the results in a few of the cases were striking when the patch-positive substances were removed, as compared with the removal of the scratch-positive substances. We believe that the patch tests were more practical because of their reliability. It was rare to see that a positive substance (by patch) seemed to play no rôle in the etiology of the skin eruption.

We agree with Sulzberger that clinically the cases of neurodermatitis disseminata differ from contact eczemas or from the group which has been labeled Type I. We also have found that in the former there is an especially high incidence of a family history of allergy. While only 3 of the cases had a personal history of allergy, there were none among the 70 cases with a Type I eczema. The number of positive patch and scratch tests were about the same as in the Type I group. We have found no proof that the site of the skin reactivity in the neurodermatitis cases was primarily of a different type from that of this group, as far as could be deduced from the evaluation of the skin tests, but it is necessary to stress that we have tested only children, and Sulzberger's cases were youthful adults.

It is clearly evident that patients with neurodermatitis disseminata (Type II) present a primary skin manifestation (the papule) which appears to be different from a contact dermatitis. Even in those cases where a feather sensitivity has been found by patch tests, which has been borne out by the clinical course, the test itself did not reproduce a neurodermatitis but a papular-vesicular eczema. This criticism could just as well be applied to the sensitivity to silk which Sulzberger and his coworkers have found because, obviously, the wheal is also not a reproduction of the disease. To say that reactions of this type, after rubbing and scratching, may give rise to the picture of neurodermatitis is conceivable, but

there is no proof that a primary urticarial reaction finally gives such a picture. However, it has been common experience that lichenified eczema resulting from a primary vesicular skin reaction may result in a clinical picture which is very difficult to differentiate from a primary neurodermatitis.

If we compare the histology of neurodermatitis disseminata with the ordinary vesicular eczema, we find that the basic findings are essentially the same. The changes in both consist of parakeratosis, acanthosis, and edema. Spongiosis (intercellular edema) is usually not found in neurodermatitis. The changes in the chorium are certainly about the same. The difference between the two is quantitative. In neurodermatitis disseminata the intercellular edema is minimum so that we do not get frank vesicular formation as in the Type I eczema. The above seems to the writer to indicate a quantitative rather than a qualitative difference between the two types of skin reactions and speaks more for a common mechanism of pathogenesis. It is of interest to note that the eczema on the face, especially the cheeks, in children with neurodermatitis resembles the Type I eczema rather than that found in the flexors.

A great deal of study is required, of course, to explain why a change in skin reactivity takes place from a Type I into a Type II, and above all why there is this marked tendency to localization in the flexors of the elbows and knees, if the whole skin is sensitive to the allergens.

THE HEREDITARY FACTOR IN ECZEMA (ATOPY)

The group of cases to be discussed here were characterized by an allergic family history. Coca⁸ has designated this factor as the most important and constant link in the atopic group.

Analysis of the 22 cases included in this group indicates that even in infancy there is a tendency for the neurodermatitis type of skin reactivity to appear in the atopic individual. If such an infant manifests his eczema long enough, even though it was originally vesicular in character, it will practically always develop into a neurodermatitis disseminata (Type II) after the third year.

Table I shows that in the atopic group we had 8 individuals with a Type I eczema between one and three years of age, and

4 with a Type II eczema in that age group. There was only one with a Type I (vesicular) eczema after three years as compared with 10 cases with a Type II (neurodermatitis) eczema after three years.

It can be said that while practically all of the atopic individuals eventually develop a neurodermatitis disseminata, only 50 per cent of the neurodermatitis disseminata cases have an atopic family history.

Patch and Scratch Tests.—Fourteen of the cases were positive by either patch or scratch tests. The total number of cases giving reactions in this group were not very much greater than in the neurodermatitis disseminata cases, but as will be seen below, the percentages of positive

patch tests were also much higher than in any other group.

Five of our children developed asthma and one had hay-fever. It seems, therefore, that the incidence of personal allergy was highest in this group.

In summing up this group of cases we seem to have individuals who manifest a particular tendency to allergic manifestations. Just as in the neurodermatitis group, there is no evidence that the fundamental mechanism responsible for the skin manifestations differs in any way from that of any other group. The relatively higher number of positive scratch tests would be partly accounted for by the greater incidence of asthma, but even the number giving positive reactions to the contact tests

TABLE I

Eczema	Number of cases	Family history of allergy	Personal history of allergy	Age of onset	Average age observed	Tests	
						Scratch	Patch
Eczema Type I	70	10 (14%)	*No cases after one year of age	Usually infancy	All ages, especially infancy	19 (27%) Usually food protein	20 (27%) Usually environmental substances
Eczema Type II neurodermatitis	23	12 (52%)	3	Usually infancy	Rarely if at all in infancy. Usually after 3 years of age	7 (30%) Usually food protein	6 (26%) Usually environmental substances
Atopic group	22	all	5	Usually infancy	3 Type I between 1 and 3 years 4 Type II between 1 and 3 years 1 Type I after 3 years 10 Type II after 3 years	11 (50%) Usually food protein	9 (43%) Usually environmental substances

* Only the cases above one year of age were included in this group because it was felt that some of the infants might later develop a Type II eczema.

reactions by patch or scratch tests were very much higher.

Nine of the cases were positive by patch tests and 11 by scratch tests. Six of the cases were positive by patch and scratch; 3 were positive only by patch and 5 only by scratch. One of the cases was positive to silk by patch test.

No particular group of substances were of especial importance in these cases as compared to any other group. Again the scratch tests were usually positive to food proteins and the patch tests for environmental substances.

It is important to note that we had 6 cases which were positive by both patch and scratch tests. This was in contradistinction to only one in the neurodermatitis disseminata cases. The percentage of positives of either scratch or

were increased. It is conceivable that in this group there is a lowered threshold for sensitization which could account for the greater number of positive tests.

SUMMARY AND CONCLUSIONS

1. Ninety-three cases of eczema in infancy and childhood have been observed. Of these, 23 were infants and the others varied in age from one to twelve and a half years, the majority being in the younger age groups.

2. The patients were tested by means of scratch and patch tests. In many instances dietary tests, by elimination, were also carried out.

There was an inverse ratio of positive reactions to scratch and patch tests made with food proteins, as compared with the ratio of such reactions to tests made with

environmental substances. Among the food proteins egg white and egg yolk evoked the greatest number of positive reactions, usually only by the scratch tests. Among the contact substances, goose, duck, and chicken feathers elicited the greatest number of positive reactions, usually by the patch tests.

The elimination diets proved of practical value only in the infantile group. Milk was found to be the most frequent etiologic agent by this method of testing.

3 Our experience has led us to conclude that patch tests with environmental substances were much more reliable than the scratch tests in determining the cause of an eczema in children. At least as far as the test substances which we used were concerned.

4 Twenty-three cases with neurodermatitis disseminata were studied. This is the clinical picture which has been referred to as Type II eczema in our previous communication. It is probably synonymous with the generalized neurodermite of Brocq or the lichen chronicus simplex disseminatus of Vidal.

This clinical picture is infrequently seen in infancy. It usually manifests itself after three years of age. In the majority of the cases, however, a vesicular papular eczema (Type I) in infancy and early childhood preceded the neurodermatitis cases. Four cases in older children were seen where the primary onset was a papular eruption in the flexors of the elbows and the knees.

Fifty per cent of the cases in this group gave a family history of allergy as compared with only 14 per cent in children showing a Type I eczema. There is a greater incidence of personal history of allergy in this group as compared to vesicular eczema.

The percentages of patch and scratch tests were about the same as in the Type I cases. Our results with patch tests were not nearly so striking in this group as in the vesicular eczemas. We believe, however, that even in this group the patch tests were more reliable and practical in tracing an etiologic agent than the scratch test.

We have found no proof that the site of the skin reactivity in neurodermatitis disseminata was primarily of a different type from that in Group I, at least as far as could be deduced from the evaluation of the skin tests.

Prognosis as far as the eventual cure is concerned is much poorer in patients with neurodermatitis disseminata than in those with vesicular eczema.

An anatomical factor such as vascular distribution might conceivably be the basis for the localization in neurodermatitis disseminata since the author has observed 2 patients in whom there was the typical localization of the neurodermatitis disseminata plus an eruption limited to the areas of hemangiomas.

5 Individuals with an atopic history show a special tendency to develop a neurodermatitis type of skin reactivity. Of the 22 patients in the atopic group, only one showed a vesicular eczema after three years of age. It can be said that while only 50 per cent of patients showing neurodermatitis disseminata have a family history of allergy, nearly all of the atopic children eventually developed a neurodermatitis disseminata.

The percentages of positive tests by patch and scratch are much higher in the atopic group than in any other group, as is the incidence of personal history of allergy. In the atopic individual we seem to have patients who show a particular tendency to allergic manifestations.

6 The mechanism of the pathogenesis and the seat of the reaction of the eczema in all of the groups discussed in this paper seem fundamentally to be the same. The skin changes are probably brought about for the most part by a reactivity between fixed antibodies in the epidermis and the allergens. There is no evidence in our work that in neurodermatitis disseminata we have a fundamentally different mechanism from that of the vesicular eczemas in that we are dealing with a primary vascular sensitivity in the papillary bodies which is essentially an urticaria. In such a conception the epidermal changes would be purely secondary to the cutis changes and caused by rubbing and scratching.

On the Influence of Heredity in Atopy. *Jour. Lab. and Clin. Med.* 12: 1135, 1927. 125 EAST 72ND. ST.

DISCUSSION

DR. A. WALZER: Dr. Peck has adopted the term "infantile eczema" in a rather broad sense, which to my mind, is far from satisfactory. While I do not like to bring up the old question of the nomenclature of eczema, still I think, if the term is to have any clinical significance at all, it might be advisable to limit it sharply to the least number of dermatoses, rather than to extend its meaning to include the diverse clinical dermatological conditions as suggested by Dr. Peck.

Dr. Peck has adopted the views of the German school, that eczema is chiefly dependent on two principals: an "idiosyncrasy of the skin", and a contact of certain exogenous etiological substances; and he applied this conception to the infantile eczemas as well. There is a tendency, in this country especially, to limit the term "infantile eczema" to a narrow group of dermatoses, which are also dependent on two principles. The first is a clinical factor, which demands that the picture must be that of an oozing, vesicular dermatitis; and the second, an immunological factor, which implies a positive personal or familial history of atopy. In other words, in our conception of infantile eczema, we take into account, in addition to the atopy, the type of the skin reaction rather than a diverse conglomeration of etiological factors and pathological mechanisms. When the expression "infantile eczema" is employed, we imply a definite clinical picture which needs no additional descriptive explanation.

Dr. Peck has included the contact dermatoses under the head of infantile eczema. Such dermatoses are not by any means infrequent in infants, and are due, as Dr. Peck has shown, to many contactants, as soaps, feathers, powders, clothes (wool, etc.), and even to the local contacts of certain foods, as vegetables, cereals, etc. (chiefly on the face). While contact dermatoses are also manifestations of hypersensitiveness, they are not atopic and not reaginic. They should not be classed with the infantile eczemas.

Under Type II eczema, Dr. Peck includes disseminated neurodermatitis and especially Besnier's prurigo. In 1892, Besnier described his "prurigo diathesique," which was later named by Rasch "Besnier's prurigo," and is more or less accepted, as a clinical entity by the French. Neurodermatitis disseminata and Besnier's prurigo have their own clinical pictures, and run their own courses, and with very indefinite etiologies, and certainly should not be classed with the eczemas.

Of course, there may be flaws in this conception of the infantile eczemas, just as well as there are objections to the one adopted by Dr. Peck; but, with our immunological knowledge in such an uncertain and indefinite state, it might be advisable, for clinical purposes at least, to limit the eczemas as suggested, rather than extend them.

Another matter relative to this question under discussion is the importance in infants especially, of the scratch and intradermal test, both of which have practically the same significance. Dr. Peck's experience with these tests have been rather poor. Our results with the intradermal tests, on the other hand, have been very satisfactory. How are we to correlate Dr. Peck's experience with ours? I think the answer lies in the proper

evaluation of the positive reaction, especially in infants.

Assuming that the technic and the extracts employed in the tests are satisfactory, a positive reaction in an infant might simply be the result of an irritable skin, which is not rare in infants, and therefore has no diagnostic significance. A positive skin reaction also signifies the presence of certain circulatory antibodies, of which there are two types. One, the precipitin, was originally described by Schloss and his associates. They showed that these precipitins occur in normal and abnormal infants, very often after the ingestion of a new food, especially egg and milk. These antibodies are not pathologic and hence not the cause of the eczema or any other sensitivity. It is probable that these antibodies were responsible for the positive reactions obtained by Dr. Peck with egg, which he could not satisfactorily explain. The other type of antibody responsible for the positive reaction is the reagin, which is present in the atopic infant as a result of heredity. This antibody is pathologic and may be the cause of the eczema.

Having obtained a positive reaction, and excluded an irritable skin factor, how are we to know which type of antibody we are dealing with? Is it the harmless precipitin, or is it the pathologic reagin? The method of distinguishing between the two is by the Prausnitz-Küstner technic. Reagins can be transferred to skin sites on normal subjects, while precipitins cannot. It is by such method of indirect testing that we have been able, not only to check up on our direct reactions, but to obtain a much larger proportion of real positive reactions in our cases of infantile eczema, more than Dr. Peck has been able in his cases.

One fact, however, must not be lost sight of. The mere demonstration of reagins is no proof that the causative factor of the eczema has been found. The symptoms must clear up on the elimination of the atopens giving the positive reactions, before they can be incriminated as the offending factors. If this does not occur, these positive reactions are only important in that they are indications of a potential sensitivity, that is, one that may yet develop at some later date in that infant.

I would like to ask Dr. Peck what procedure he follows when an infant with a suspicious eczema first presents itself. Does he begin his tests immediately? Our approach in a case of an infantile eczematous eruption is as follows. Seeing a case of an eczematous dermatitis for the first time, a complete history is taken and physical examination is done. We immediately institute local treatment, employing daily bandaging, if necessary of the entire trunk, extremities, face and scalp. By this procedure, we hope to control the seborrheic or contact dermatoses, which may simulate the infantile eczema. This local therapy also controls the secondary or superimposed irritative dermatitis of a real eczema. If after a certain period, the improvement ceases to progress, we begin testing, either by the direct, indirect, or very frequently by both methods, still, however, keeping up with the dressings. If the condition clears up without the testing, we wait for possible recurrence before testing is begun. By this method we have been able to control a great many of our cases of infantile eczema.

THE NEED FOR CONSERVATISM IN THE TREATMENT OF BENIGN UTERINE BLEEDING IN WOMEN UNDER 35 YEARS OF AGE

HERBERT F. TRAUT, M.D.

From the Department of Obstetrics and Gynecology, New York Hospital and Cornell Medical College

In the last few years we have been increasingly impressed by the frequency with which we are consulted by young women who have lost the fundus of the uterus or the physical function of that organ following surgical intervention or treatment with radium or x-ray for benign pathological conditions usually associated with abnormal vaginal bleeding. This situation occurs with sufficient frequency to cause us to feel that either there must be a lack of appreciation among at least a part of the medical profession concerning the less radical forms of treatment and the procedures available for curing myomata uteri, endometrial polypi, and the hormonal bleedings, or that we may be somewhat callous in our attitude toward the importance of conserving the uterus. Therefore, it seems important to reconsider our therapy and to sound a note of conservatism.

What are the causes of uterine bleeding in women under thirty-five years of age that are definitely of benign origin and which should, if possible, be treated conservatively? They group themselves quite naturally into two distinct categories: (1) those associated with recent pregnancy, and (2) those independent of pregnancy. In the former group we encounter

- 1 Retained fetal membranes
- 2 Hydatidiform mole
- 3 Tubal pregnancy
- 4 Pregnancy in one horn of a bicornuate uterus
- 5 A group of entities having to do with abnormal placental conditions, viz., placenta praevia, low implantation of the placenta, and premature separation of the placenta

In the latter group we most often see

- 1 Hemorrhage due to hormonal imbalance such as endometrial hyperplasia, irregular shedding of the endometrium and irregular ripening of the endometrium
- 2 Polypoid changes of the fundal or cervical mucosa
- 3 Myoma or adenomyoma uteri
- 4 Adnexal disease

The causes of benign bleeding associated with recent pregnancy are, we believe, treated for the most part with conservatism and a view toward preserving the child-bearing function. Retained fetal

membranes are removed from the uterus immediately in those who are afebrile, but in the presence of infection the patient is palliated until the inflammatory process subsides, unless the hemorrhage is so profuse as to endanger the patient's life, when the danger of spreading infection becomes secondary and immediate removal of the offending tissues is definitely indicated.

Hydatidiform mole is removed from the uterus, and then the patient is carefully watched for a period of many months for recurrence of bleeding, but more particularly by means of the Aschheim-Zondek test to determine whether or not the trophoblast is proliferating or degenerating, as an index of whether we are dealing with benign or malignant sequelae.

Tubal pregnancy and pregnancy in a bicornuate uterus constitute a sufficient menace to the woman so afflicted that frequently surgical intervention is indicated, the former usually early in pregnancy, the latter somewhat nearer term.

The group of conditions associated with placental anomalies is also usually treated according to indication. Low implantations are differentiated from placenta praevia, and the former allowed to follow a spontaneous course. The treatment of placenta praevia is a field in which great difference of opinion exists, but one can say that there is an increasing use of those procedures which aim at a close approximation of normal delivery with the introduction of the Voorhes bag or the Braxton-Hicks maneuver only when necessary, and with less and less resort to cesarean section except perhaps in the primipara with central placenta praevia and a long closed cervix.

Unfortunately, in premature separation of the placenta, particularly when it occurs during labor, we are confronted with the dangers associated with intramuscular hemorrhage, so that we must often resort to abdominal section and anterior hysterotomy. But here again we are conservative, because we do not remove the uterus until its power of contraction has been tested by use of external massage, intravenous pituitrin, etc. When it does contract, it is allowed to remain. On the other hand,

should it fail to do so adequately, particularly when there is the subperitoneal mottled appearance which indicates extensive interstitial bleeding, we do not hesitate to remove the organ.

This short review of the accepted forms of treatment of the various kinds of bleeding associated with pregnancy is convincing in its simple and straightforward conservatism.

Our modern therapeutic trends in the benign pathological conditions of the uterus unassociated with pregnancy are not so conservative and tend much more toward destructive procedures. This statement holds especially for refractory hemorrhage due to hormonal imbalance and that type associated with fibroid tumors of the fundus. The use of radiation and hysterectomy in the treatment of these two groups of patients is, in our opinion, often ill-advised. That these are the methods of choice in some cases cannot be denied; but in many others to which they are now applied they seem unjustifiable, even radical. There are serious objections to the uncritical use of radium, x-ray, and hysterectomy in the treatment of benign conditions of the uterus in young women when employed without sufficient indication, as we have reason to feel is often the case.

We have in mind two recent patients whose stories will serve as illustrations of a great many others. R. V. was 25 years of age and unmarried. Four months prior to her first visit to the New York Hospital she had consulted a physician because she was suffering from profuse menses. A diagnosis of myoma uteri was made, and the patient treated with a series of x-ray exposures through four portals, two front and two back, concentrating on the pelvic organs. These did not effect a cure after four months, consequently the patient sought further medical assistance and came to this hospital. She was found to have a hemoglobin of 58 per cent (Sahli). There was no other abnormality excepting numerous small myomata of the uterus. Unsuccessful efforts were made to learn the dosage of x-ray given by her former physician. She was transfused in the hope that she had not had a sterilizing dosage, and a multiple myomectomy was performed. The menorrhagia has not recurred; but now, six months later, the patient is suffering from severe menopausal symptoms, the latter undoubtedly due to the x-ray treatment. No comment is necessary to indicate what a catastrophe this situation is in the life of the patient, and what a commentary it is on the unwise use of radiation therapy.

Another patient, R. H., 27 years of age, has been married two years but has never been pregnant. One year ago she noticed a tumor of the lower abdomen, and being a trained nurse, sought the advice of one of our leading gynecologists. The diagnosis was myoma uteri. There was no anemia, no abnormal menses, no mechanical

symptoms of any sort. She was advised to have a hysterectomy, the only possible justification for which, from our point of view, being the possibility of future difficulty. A subtotal hysterectomy was performed in a masterly manner; the suspension of the ovaries was carefully done. The uterus contained two subserous myomatous nodules 4 and 6 cm., respectively, in diameter. Laboratory examination revealed that these were the only ones present in the uterus. This patient is now suffering from unmistakable menopausal symptoms. She has not only been deprived of the possibility of having children, which she ardently desired and has never ceased to regret as an impossibility, but has an additional handicap in this passing of ovarian function.

We realize that such ideal cases for myomectomy as these here related are somewhat rare. But what a commentary it is that when they do exist we are so deeply rutted in our stereotyped radicalism that we not only do not recognize them, but worse, do harm beyond our own or nature's power to repair.

The profession is accustomed to a conservative attitude toward acute pelvic inflammatory disease and the frequently associated uterine bleeding, because we have learned that palliative measures are safe and that the ultimate results of this form of treatment are far better than the once common salpingectomy and drainage of the acutely inflamed pelvis. In a similar manner, we have learned to respect ovarian tissue, because the rigors of premature menopause have been brought forcibly to our attention. But despite these lessons with regard to neighboring organs, we have been extremely slow to adopt a similar attitude toward the fundus of the uterus, particularly when the diagnosis is myoma uteri or hyperplasia of the endometrium. Perhaps it is of less moment that we should do so; but that it is of great importance in the first two decades of sex life no one can doubt who comes in contact with any considerable number of women who have had hysterectomy or pelvic radiation before the menopause.

There are several major reasons why we should be slow to remove the uterus. The first is the preservation of normal physiological relationships. Even in the hands of those possessing excellent surgical ability, great care is required to suspend the ovaries so that their hormonal function can be maintained after the lapse of a year or two. In the presence of slight handicaps such as old puerperal inflammatory thickening of the mesovarium, failure is frequent. This is evidenced by the high incidence of premature menopausal symptoms following

hysterectomy This result is usually explained by postulating a disturbed vascular supply to the ovaries

Another reason of major importance is the preservation of the child-bearing function All of us have seen young women lose their uteri because of an offending myoma or two, or have seen the onset of the menopause following radiation of a refractive metropathia hemorrhagica, because those methods seemed to their medical advisors to be the only means at their disposal in dealing with the condition For these patients the whole course of life has been altered upon relatively slight indication, because the medical profession as a whole does not recognize and employ the more moderate means at its disposal for accomplishing a better result

A third reason for conservatism, and one which is urged upon us by the psychiatrist, is the incidence of abnormal psychological states following the loss of the uterus, even though not definitely accompanied by the menopausal syndrome

Historically it is interesting to note, and quite natural, that the earliest and what has come to be the commonest operation for the cure of myomata, should have been supravaginal amputation of the uterus The relation of the blood supply to the cervix forms a natural pedicle which it is logical and convenient to sever For many years removal of the uterus was accompanied by removal of its appendages, the fallopian tubes and the ovaries, and no adequate technique for the suspension of the cervix was known However, the rigors of the precipitate menopause, the prolapse of the vagina with its accompanying organs, stimulated surgeons to devise ingenious methods for preserving the ovaries and of so fixing the cervical stump that vaginal relaxations did not occur Hysterectomy today is a simple and relatively safe operation which yields good results when performed in the presence of adequate indication It is with the application of the operation to the indication that we have come to err on the side of radicalism It is to be hoped that the next step that we as a profession may take in the evolution of our treatment of the benign causes of uterine hemorrhage in the young woman may be one designed to preserve as many of her functions intact as is consistent with her health and wellbeing

Plastic operations for the removal of tumors from the uterus in an attempt to save the organ and restore its normal function

have never been popular As long ago as 1897, W Alexander¹ of Liverpool published a careful account of his methods and results in a considerable series of patients Since that time sporadic attempts have been made both in England and America to bring before surgeons the importance and advantages of myomectomy as contrasted to hysterectomy in selected cases, with very slight response on the part of the profession The reasons for this apathy seem to lie in

- 1 A lack of appreciation of the importance of conserving the uterus
- 2 Lack of the fundamental principles of plastic surgery which are necessary to make the operation a success
- 3 The recurrence of tumor growths following the operation
- 4 The fear of rupture of uterine scars in subsequent pregnancy

Our newer knowledge of hormonal relationships, as well as our more complete follow-up of patients, is bringing to our attention the necessity of a more conservative attitude toward the body of the uterus in women under thirty-five years of age In the light of recent work upon the subject, it seems possible that there is a physiological balance to be maintained between the endometrium and the ovary, and further, that the complete removal of the former is not necessarily followed by undisturbed function of the ovary The surgical technic necessary to accomplish a good result with myomectomy is at our disposal It has been brought to our attention principally through the work of Victor Bonney² of London Various modifications of his technic and some improvements have been added by various workers in this country

The recurrence of tumors is a stumbling block that can only partially be removed However, thoroughness on the part of the operator can accomplish a great deal, as we have learned in our series of cases It is undoubtedly worth while, and we should be content, if we can conserve the uterus even a few years, to allow the young women the opportunity of motherhood and the physiological and psychological advantages of possessing an intact uterus In a surprising number of cases there is found to be no serious recurrence of tumors We must therefore come to the conclusion that it is unjustifiable to assume that if a patient has myomata uteri she will have more tumors if those present are removed A conservative attitude demands that she be given the opportunity to heal the body of

her uterus, if this is at all possible, rather than that it be removed from her. We shall never become expert in the performance and application of myomectomy unless we practice it. We feel that the rarity of its use in our larger clinics may be an indication of a lack of appreciation of its possibilities.

The fear of rupture of uterine scars would seem to have been overemphasized, as Bonney,² Waldeyer,³ and others have published large series of cases in which myomectomy had been performed and subsequent pregnancy and labor normally carried out. It is obvious that a poor union of tissues is a menace in the uterus, whether it follows myomectomy or cesarean section. Sanger taught us how to suture the uterus at cesarean section. Bonney has taught us how to suture the uterus at myomectomy. Both apply sound principles of plastic surgery, avoid dead spaces, prevent hemorrhage and oozing, and accurately coaptate layers of tissue. Just as we have learned that the time-honored dictum "once a cesarean section, always a cesarean section" is unsound, so will we overcome our old phobias concerning myomectomy scars in pregnancy. It is very important, however, that a suitable time-interval elapse between myomectomy and the imposition of the strain that pregnancy is sure to place upon suture lines. Contraceptive measures make this possible with intelligent patients.

With the advent of deep x-ray therapy and the wider distribution of centers where it is available, as well as with the introduction of radium, there has come an increasing use of radiation in the treatment of benign bleeding of the uterus, particularly when myomata and hyperplasia of the endometrium or other hormonal imbalances are the root of the difficulty. It is widely used even in young women. This is more open to criticism than hysterectomy, because at best it is a crude method in the sense that it is not specific. It is impossible even for experts to confine its effect to those parts which are the seat of the immediate difficulty. The work of Pemberton,⁴ Ward,⁵ Dean,⁶ and others illustrate that radium and x-ray therapy are not un-mixed blessings, even in women suffering from conditions, such as carcinoma of the cervix, which are sufficiently grave to warrant the use of these agents. Furthermore, they point out that many of the untoward effects appear years after treatment is normally considered complete. It is true that

they refer to women in the cancer-bearing age principally, but Pemberton,⁴ Dean,⁶ and Phaneuf⁷ all refer as well to the use of x-ray and radium in the treatment of uterine fibroids and metropathia haemorrhagica in young women.

We speak of "shrinking" myomatous tumors when we know that highly differentiated connective tissue is most resistant to radiation. We do actually shrink them, because we limit their blood supply by producing an endarteritis of the blood vessels on the one hand, and on the other (and more important), we destroy the hormone-producing elements of the ovaries, which have a growth-stimulating influence. But we not only affect the blood supply of the tumor, or the bleeding endometrium; we affect the whole uterus, parametrium, base of the bladder, and lower bowel. In addition, we remove the hormones of the ovary from the body. A small dose of radium (500 to 750 mg. hrs.) is often recommended as sound therapy in the intractable bleeding of puberty. The x-ray has similar proponents. Yet how often we see patient, having had these "small dosages," who one, two or three years later are suffering from their original complaint or the opposite, amenorrhea, oligomenorrhea, and sterility. Inasmuch as every gynecologist has at his command more moderate therapeutic agents which are effective, we dispute the justification for the widespread use of these more radical forms of therapy. We are aware that these older and less positive forms of therapy require greater patience, a longer period of treatment, and that sometimes the patient seems quite unresponsive; and yet metropathica hemorrhagica is admittedly a self-limited disease. It is impossible to find an instance in which the subject has succumbed to an uncomplicated attack. Therefore, palliation, without introducing a form of therapy which can be of permanent harm, is absolutely indicated.

Are x-ray and radium therapy ever justifiable in young women? Under certain circumstances they certainly are. In individuals who cannot, for whatever reason, undergo laparotomy we should resort to it if the tumors or bleeding points are a real menace to the patient; but then only after palliative methods have failed on prolonged and consistent trial. However, to apply it with relative indiscriminination, as is being done in many centers, simply because this form of treatment gives immediate relief from the ailment or because it

appeals to the imagination of the patient, is so unjustifiable as to border upon the unethical

The simple methods of therapy, such as hygienic measures, snake venom injections thyroid therapy, iron ammonium citrate and transfusion, as well as those of good conservative surgery, still have more to offer the majority of women under thirty-five years of age than have hysterectomy and radiation therapy. The profession must accept its responsibility in securing for the patient the greatest good over the greatest possible span of years. Thus we believe will necessitate a decrease in the employment of radiation of the body of the uterus and removal of that organ in young women suffering from bleeding and tumors of benign nature.

Metropathia hemorrhagica, myomata and other benign causes of uterine bleeding in women over forty years of age form an entirely different problem, for the menopause is imminent, the induced climacterium is not so severe, the chances of child-bearing are remote, and the incidence of psychiatric conditions much lower. It is the difference in therapy in the two age groups which we wish to emphasize. In doing so, we hope to induce similar caution and conservatism in our therapy of the benign conditions of the uterine fundus

unassociated with pregnancy such as we have learned is safe and wise in those in which pregnancy is the instigating factor.

SUMMARY

An attempt has been made to contrast the conservative therapy commonly used in benign hemorrhage associated with pregnancy, with the radical therapy so often in vogue for the treatment of vaginal bleeding when pregnancy is not a part of the picture. The former is definitely conservative, the latter just as definitely destructive. We feel that there may be justification for the radical point of view in women at or near the menopause. On the contrary, we wish to bespeak for the nonpregnant women under thirty-five years of age more of the consideration and conservative viewpoint which we accord her pregnant sister.

PENCRAFT AS WITCHCRAFT

Science articles intended for newspaper readers must be written more or less on a witchcraft basis," says no less an authority than Austin H. Clark, biologist and member of the staff of the Smithsonian Institute, who has for several years handled the press service of the American Association for the Advancement of Science. "We are prone," he remarks, "to regard ourselves as wholly free from the mental shackles of superstitions that characterize savages and our own ancestors. But," he adds, "while continuing to flatter ourselves with this comfortable belief, let us constantly remember that the human mind has not changed and that all the beliefs that we deprecate in the so called savages and try to forget in relation to our own forebears exist to day in most newspaper readers—and also in us—in more or less modified form."

'Successful publicity for science is based first of all upon the recognition of people for what they are. It is futile to assume that we can make them over into what we would like them to be.'

He also stresses the fact, as he is quoted in *Editor and Publisher*, that the public is interested in personalities and emotions, while scientific men believe at least that they appreciate the world on the basis of determined fact. Every scientific article written for popular consumption, he says, must be tied to some personality. And, 'in addition to being tied to some personality it must have as a keynote—love, hate, gain, loss, mystery, or some other basic emotional concept.' His experience may be useful to those who write or speak on medical subjects for the press or the radio.

A TRUCKLOAD OF HEALTH

Health is taken to the rural regions of Maryland in a "Healthmobile," a big truck carrying a complete outfit to set up a children's and infants' clinic wherever it stops. It has a doctor, a dentist, and a public health nurse, facilities for examinations, a junior dental chair, and a moving picture outfit with health films. We are told that last summer seven counties were visited in an eleven week tour covering 1,400 miles. A total

of 89 health conferences were held for the examination of babies and children under school age, 1,589 children being examined, an average of around 30 each day.

The aim of the conferences is to show mothers how to keep their children well. No medical treatment is given, children in need of medical care being referred to their own family physician.

A PRACTICAL DISCUSSION OF THE IMPORTANCE OF
MEDICODENTAL COOPERATION

THEODOR BLUM, D.D.S., M.D., F.A.C.D., F.A.C.S., F.I.C.D.

New York City

The dentist of to-day—and the author does not wish to use the title “dental surgeon” because it is misleading and only too often used to mislead—is trained in the recognition and treatment of diseases of the mouth, jaws and teeth. The majority of dentists are in general practice, while a smaller number devote their practices to dental specialties, on one hand, in the mechanical fields like porcelain, crown, bridge, and plate work; others, practicing periodontia (the treatment of diseases of the gums), orthodontia (the art of regulating teeth), and finally, oral surgery. The oral surgeon is usually expected to be a graduate in medicine also. However, with the marked advance of dental education, the oral surgeon who confines himself to minor oral surgery will after graduation and post-graduate studies be trained well enough to practice his specialty satisfactorily. It is timely to state here that the writer believes in a medically educated dentist and not in a physician practicing dentistry as a specialty, because the degree of M.D. does not give him the medical practical experience, while the modern dental school gives the dentist a medical foundation. Furthermore, if the physician would practice dentistry as a specialty, one must require of him the regular internship in a hospital, at least three years of general medical practice before he could enter the study and practice of dentistry as a specialty.

One often hears physicians remark that they have examined the patient's mouth and that certain teeth should be removed because they carry a gold crown or because a tooth is discolored. Such findings, of course, do not condemn such a tooth because it may be good and serviceable despite its condition. To-day the examination of the mouth is not complete when only using a mouth mirror and an explorer, but must include aside from the ordinary clinical examination an intra- and extra-oral x-ray study including bite-wing films, a vitality test, and transillumination. Such the physician cannot accomplish as he lacks the proper training.

The dentist also believes in the principle of periodic health examination of the

mouth as well as any other part of the body. “In fact, the dentists have appreciated this for more than fifteen years and have created the dental hygienist whose duty it is to subject a patient's teeth to prophylactic treatment and call the dentist's attention to the presence of any pathological condition. The author goes still further and believes that once a complete record of a patient's mouth has been taken by means of x-ray, pulp test and transillumination—aside from the usual clinical records—the so-called bite wing x-ray examination which only shows the crowns and the neck of the teeth should be taken annually and only those teeth completely x-rayed which are devitalized. This x-ray examination in combination with the periodic treatment by the dental hygienist well trained in the recognition of the pathological conditions about the mouth will prevent many conditions, a successful treatment of which at the present time is either difficult or impossible.”*

To prove the necessity of cooperation between the two professions and their respective specialties, it is important to call attention to individual cases. Vincent's infection of the mouth, for instance, cannot be treated by the physician or rhinologist; even if it also affects the tonsillar region the treatment of the mouth must be left to the dentist or the periodontist because the daily instrumentation of the free gingiva is the most important part of the treatment with which the physician is not familiar.

How unfamiliar the rhinologist and general surgeon is with the removal of a salivary calculus, is shown by the fact that recently one suggested the insertion of ligatures in the floor of the mouth to steady the field of operation, and others, as a rule, suggest the removal of the submaxillary salivary gland when the stone is near the same. The writer has under his observation a fairly large cyst in the left maxilla, which was operated on by a general surgeon a few years ago, who never paid any

* Theodor Blum: More Common Diseases of the Teeth and Jaws, *Bull. New York Academy of Medicine*, August, 1931.

attention to the teeth which are the causative factors and left in position devitalized teeth which have never been treated. If patients who are suffering with osteomyelitis of the jaws are treated by a general surgeon, pathological fractures and extreme loss of bone is usually the result of their radical procedures.

Although very little is known about tumors of the jaws, the physician is apt to pay less attention to them particularly in the early stages, as the author experienced with a case of a mixed tumor of the salivary gland type of the palate, where the physician insisted on leaving it alone because it did not bother the patient.

While at present the oral surgeon usually acts as the dental consultant, particularly where oral focal infection is considered, this duty will in the near future, with improved dental education, be relegated to the general dental practitioner. At any rate, it should never be a question of instructing one or the other to do this or that, but whatever treatment is outlined for a patient should be based on mutual understanding and be the result of a thorough discussion.

For instance, many times patients present themselves with inflamed gums and while most of these conditions are frequently due to neglected mouth hygiene, they are nevertheless at times oral symptoms of blood dyscrasias, diabetes, etc., in other words, such a case cannot be treated without consultation with the family physician. The conservative operation of root resection should not be performed without ascertaining the state of the patient's general health, so as not to burden impaired health with the retention of a questionable devitalized tooth. The exposure or removal of malposed teeth, the removal of salivary calculi, although as a rule minor operations, should not be performed without getting all necessary information from the physician. In treating the more serious cases of osteomyelitis, Ludwig's angina or tumors, the cooperation of the physician will not only be beneficial to the patient, but also of great assistance to the operator. On account of the close proximity of the maxillary antrum to the mouth and teeth and the often misleading symptoms, a close understanding between the rhinologist and general roentgenologist, and dentist or oral surgeon is quite evident. Many errors which have occurred on both sides have been due to lack of appreciation of the

above. When dealing with the problem of oral focal infection, the cooperation of the two practitioners must determine the necessity of conservative or radical treatment. Although frequently the diagnosis of trifacial neuralgia seems quite clear, the radical and most successful operation of subtotal section of the sensory root of the fifth nerve (Frazier), or even an alcohol injection should not be resorted to under any circumstances without a thorough examination of the mouth, jaws and teeth, so to finally exclude the possibility of an error in diagnosis. At any rate, the treatment of such a condition must be based on the result of a consultation between the neurologist, neurosurgeon, and dentist.

To sum up the writer's particular standpoint, namely, the one of the oral surgeon, "is he justified to operate without consulting the family physician in case of heart, lung, kidney, or other disease in the field of internal medicine? I am personally quite aware of, and have been grateful on many occasions for assistance received from general dental practitioners and dental specialists in dealing with cases requiring root amputation, alveolotomy, surgical prosthesis, and treatment for fractures. No matter how well educated medically the oral surgeon may be, the pediatrician will always prescribe the formula for the feeding of the infant to be operated upon for harelip and cleft palate. Ophthalmology when dealing with a possible oral focus, rhinology when in doubt about the etiology of a sinus affection, and otology where there are referred pains, are branches of medicine that assist us in the proper care of our patients. To day the oral surgeon also acts as a diagnostician and, therefore, certain soft tissue lesions of the mouth necessitate an examination of the skin and other mucous membranes by the dermatologist. The general surgeon in case of serious accidents, the brain surgeon in trifacial neuralgia, and even the obstetrician where lesions of the gingiva appear during pregnancy, must be consulted in the interest of our patient. Finally we come to the roentgenologist when we suspect an expression of facial bone lesions in other parts of the skeleton or a metastasis to the lungs or distant regions. The importance of seeking advice and treatment, for our cases, from the specialist in radium and x ray therapy is evident."

*Theodor Blum. What is Oral Surgery?
Jour. Dental Research, April, 1933

If we now believe in the importance of this cooperation, we must not stop with applying the same to our private practice, but must attempt to establish a similar relation in hospitals. The medical board should insist upon the creation of a complete dental department under the supervision of a general dental practitioner and the appointment of dental internes and hygienists. Only too often a dental specialist, particularly an oral surgeon, is put in charge of the dental department which results in almost entire neglect of the most important branches of dentistry, namely, dental operative (fillings) and prosthetic work. Every patient admitted to the hospital must receive a dental examination and have the findings recorded on a special dental chart.

"The dissemination of knowledge by exchange of thought and experience among oral surgeons and other medical and dental specialists, as well as among general medical and dental practitioners, at frequent conferences, where cases could be presented or reported and discussed freely and honestly by all participants, would practically reach the ideal, if the effort were supported by an institute where not only all types of pathological laboratory exami-

nations could be made, but which would also act as a registry for the collection of material for the further study of any subject in our field. The above refers particularly to conditions about the mouth for which purpose The New York Institute of Clinical Oral Pathology was founded, which is devoted to these principles and holds monthly conferences for the purposes outlined.

In conclusion the author wishes to say that every dentist when examining a new patient should take advantage of this opportunity to refer to the importance of a thorough medical examination and insist for his own benefit as well as that of the patient on a general medical examination before undertaking anything but emergency treatment. The physician, on the other hand, after a thorough study of his patient should stress the importance of the examination and treatment of conditions of the mouth, which on account of his limited dental information he is not in a position to make. Only frequent discussions of the problems confronting the two professions will finally bring about a better understanding of both and better care of the patient.

101 EAST 79TH STREET

FOOD HANDLERS NO LONGER EXAMINED

Not worth the cost. That seems to be the verdict of the health authorities of New York City on the yearly examination of food handlers, and the examinations have been abolished, except for handlers of milk. As reported in the *A.M.A. Journal*, Dr. John L. Rice, City Health Commissioner, emphasized in a statement that hereafter greater attention would be given to the personal hygiene of food handlers and to the entire matter of food sanitation.

The action, reversing a policy adopted eighteen years ago, was based on two objections. First, it was said that a clean bill of health given to a food handler may have no significance a week later. A second objection arises from the fact that the presence of certain infectious conditions can be determined only by repeated painstaking examinations, which are practically impossible; the cost would be very great and the benefits to the public small. Dr. Rice declared, in that hundreds of thousands of dollars would be spent to discover at most only a few potential spreaders of disease.

It is also pointed out that the health department has more effective measures available for dealing with the possible spread of infection by food handlers. Overreliance on the physical examination of food handlers has brought with it a diminishing emphasis on personal hygiene and matters of general sanitation, Dr. Rice continued. It is proposed now to lay more emphasis on the simple matter of frequent hand-washing and on sterilization of eating and drinking utensils. The Commissioner stated that during 1933

the department had issued 361,289 cards to food handlers, the activity taking up the full time of a considerable number of clerks as well as the time of a physician supervisor. To keep the cards on which the results of examinations are recorded, filing cabinets and valuable space are required.

Altogether the commissioner feels that this is an unprofitable procedure, for the records, he says, have little value. Judged by the criterion of reducing disease and death, the cost of the health examination of food handlers is enormously out of proportion to the returns yielded to the people of the city.

A recent list shows that there are now 139,309 physicians in the United States in active practice. Of these 8,698 are over 69 years old; 3,608 are on the staffs of hospitals; 42,154 are specialists of various kinds, including 12,152 surgeons, 3,501 internists, 3,529 pediatricians, 349 psychiatrists, and 549 public health workers. Of the specialists, 21,644 (51.3 per cent) are in cities of 100,000 population or over, while 35,899 general practitioners (38.3 per cent) serve cities of similar size. The figures also show 65,790 dentists, 8,192 osteopaths, and 5,449 chiropractors.

Doctors who participate in the panel system in England are paid \$2.25 a year for each insured person on their list, and for that sum make as many sick calls as are required during the year. The average number of insured persons on a physician's list is about 1,000.

THE EARLY RECOGNITION OF PERIPHERAL VENOUS THROMBOSIS

MYLER A. RABINOWITZ, M.D., and IRVING N. HOLIZMAN, M.D.

From the Medical Service of Dr. Myler A. Rabinowitz, Jewish Hospital of Brooklyn

Sudden death from pulmonary embolism is practically always the result of peripheral venous thrombosis. It is our purpose to discuss the early recognition of the latter in an effort to prevent the former.

Numerous excellent statistics show that peripheral venous thrombosis is very common in surgical and medical conditions, yet probably not diagnosed during life in the majority of the cases. Statistics further show that a marked increase in venous thrombosis not only in surgical but also in medical conditions has occurred in the last decade. The result has necessarily been a tremendous increase in the number of fatal pulmonary emboli. Singer states that in medical conditions pulmonary embolism has increased from 1.2 to 3.0 per cent and that fatal pulmonary embolism has increased from 0.13 to 0.65 per cent. Payr states that fatal lung emboli constitutes 5.7 per cent of all deaths in major surgical operations. We do not believe in quoting a multiplicity of statistics, as these can be of value only in proportion to the diagnostic skill of the reporter and the thoroughness of the postmortem examination.

This great increase in venous thrombosis and pulmonary embolism cannot entirely be attributed to the increasing number of abdominal operations, since a great increase of venous thrombosis and embolism has occurred in medical conditions as well. The predisposing factors are numerous, but in themselves they do not appear sufficient to produce venous thrombosis. A constitutional factor would appear to be most important. It may well be that venous thrombosis is a form of allergic reaction—a reaction of vein endothelium to plasma due to a changed reaction of the organism, a response to abnormal tissue proteins—whether arising in inflammatory tissues, operative wounds, or tissue necrosis, no matter what its cause.

A study of the individuals in whom such thrombosis occurred revealed three very important facts. First, most occurred in the fifth and sixth decades, especially between the ages of 40 and 55, somewhat later in life in the males, but on the whole

more frequently in females. Second, these persons usually possessed a *pyknic habitus*, had a *pasty pallor* to the facies, were inclined toward marked obesity, and showed evidence of increased vagus tone—respiratory irregularity, bradycardia, and dermographism. Others have noted that they were thyroid-resistant in their failure to react with tachycardia to the use of thyroid extract. Third, they were markedly hypersensitive to pain, a feature which must be most emphatically stressed. They do not spontaneously complain of pain, and it is only by daily routine questioning and examination that one may elicit the two most important evidences of venous thrombosis—pain and tenderness.

Factors, previously too greatly stressed, are infection and mechanical conditions. Localized inflammation may spread to a vein directly or by the lymphatics as in puerperal, otitic, or anginal thrombophlebitis sepsis. The infected thrombi in these latter are secondary to a phlebitis, are frequently parietal in extent, relatively small, particles break off readily and lead to bacteremia and metastatic suppurative foci in the lungs and elsewhere. Chills with high steeple-like rises and sharp descents of fever usually occur. Treatment consists in eradication of the primary focus and exclusion of the involved veins from the circulation. This type of septic thrombophlebitis is not germane to our discussion. That infection plays a minor rôle in the usual type of venous thrombosis is evidenced by the fact that it is no less frequent in clean surgery and medical conditions and occurs more frequently in the presence of nonoperated uterine myomata than in the operated myomata.

That mechanical factors play a rôle in the production of venous thrombosis, especially of the lower extremity, is not to be denied, but the mechanical factor becomes important only in the predisposed. Confinement to bed over a week, whether by operation, infection, or nonsurgical disease, conditions of heart failure, especially when attended by lowered systolic blood pressure or auricular fibrillation, and local conditions of the vein, such as re-

tarded return circulation, phleboscclerosis or varicosity, play their part and give important indications for preventive treatment. The factors favoring thrombosis of the left lower extremity over the right will not be discussed at this time.

Familial predisposition has usually not been sufficiently emphasized. This may depend on hereditary vein conditions, humoral factors or a tendency to allergic response of a peculiar type. In one family, a sister developed thrombosis on three separate occasions following pregnancies or curettage, another sister developed thrombosis following laparotomy for ectopic pregnancy, a brother following an operation for hernia, and a first cousin died of pulmonary embolism ten days after an appendectomy. In another family the patient has had recurrent thrombosis, and three siblings have died of postoperative pulmonary embolism. Schnitzler mentions a mother and two daughters having venous thromboses and pulmonary emboli; he cites another family of three brothers with the same condition.

Variations in site and extent of the venous thrombosis determine its ease of recognition, the tendency to embolization, and the extent. A thrombus completely occluding a vein for a considerable distance, firmly adherent to its walls, involving a vein of small caliber, or firmly attached above and growing toward the periphery will more readily give rise to edema, less readily embolize, and when it does embolize will usually block only a small pulmonary artery branch. It will, therefore, be more readily recognized locally or be less apt to give rise to fatal pulmonary embolism. Such conditions are more usually met in postpartum states, cachexias, medical conditions, and after the injection treatment for varicose veins.

A thrombus only partly attached to the vein wall, of great length, growing centrally, involving a vein of very large diameter such as the saphenous or the femoral, may be less often accompanied by edema, may be readily detached, and when embolism occurs, the embolus is frequently large enough to obstruct the main trunk of the pulmonary artery or one or both of its large branches and cause sudden death. This type of embolism is more apt to occur when no precautions have been taken and at a time when the patient is considered convalescent—sutures removed, patient out of bed, waiting to be taken home or soon after arrival at home.

Fatalities usually reveal a coiled thrombus in the trunk or main branches of the pulmonary artery, and when unrolled, the emboli usually measure over 35 cm. and have a diameter the width of the saphenous vein. One frequently reads in autopsy protocols of fatal cases of pulmonary embolism where examination of the larger veins in the lower extremities proved negative, or the fatal embolism was attributed to thrombosis of pelvic veins. Naturally, a thrombus which now occupies the pulmonary artery can no longer be present at its site of formation. Should the post-mortem investigation be thorough and extended to the smaller veins of the calf and leg, the remnant of the original thrombus, the cause of the fatal embolism, will almost always be uncovered.

From a clinical point of view the following data become highly important: recognition of the predisposing constitution, circulatory and local factors favoring thrombosis, realization that thrombosis usually occurs at the beginning of the second week of confinement to bed, that extensive thrombosis may occur within a few hours, and that lung embolism is especially frequent about the tenth or eleventh day. It therefore follows that the early recognition of venous thrombosis is of prime importance.

FEVER.—The presence of fever in a postoperative or medical condition is usually in itself of no diagnostic value, because other causes for fever may be difficult of exclusion. Venous thrombosis without phlebitis may per se give no fever. Any slight fever in the postoperative state without assignable cause, particularly at the postoperative site, even in the absence of pain in the lower extremities should be cause for suspicion. The temperature is usually subfebrile, transient, and unnoticed. The fever in thrombosis, without phlebitis occurring later, is probably due to minute broken down thrombus particles thrown into the blood stream. When secondary infection of the thrombus occurs, the fever becomes continuous; when accompanied by so-called septic thrombophlebitis with purulent clot, an irregular septic fever occurs, frequently with chills, and steeple-like rises and sharp descents. Later on, fever may be due to lung infarction, bland or infected. On the whole, fever is of very little diagnostic value in the average case of bland thrombosis, as complications which may in themselves cause fever are frequently present.

PULSE INCREASE—Pulse increase may be absent. When present it is frequently of no value, as it can be assigned to some other cause than venous thrombosis.

PAIN—Pain in the groin, thigh, calf, below the inner malleolus, or in the sole of the foot is of great importance when complained of in any bedridden case, medical or surgical, especially if accompanied by fever not otherwise explained. Usually the patient is naturally hypersensitive or made so by the use of sedatives or narcotics, and the complaint is not made and must be elicited by close daily questioning during that period when venous thrombosis usually sets in.

A man, aged 52, was operated upon for direct inguinal hernia. Two weeks later he suddenly complained of severe pain in the epigastrium. His skin was pale, cold, and clammy. Physical examination of the chest and abdomen was negative except for slightly diminished intensity of the heart sounds. The clinical picture suggested coronary closure. The temperature rose to 100° F. The next day, a few crepitant rales over the right posterior chest and marked tenderness in the right calf were noted. Upon questioning, the patient admitted having felt pain in his right leg two days prior to the attack, but did not think it sufficiently severe or important enough to mention. The lower extremities were immobilized; edema developed and subsided in two weeks without further recurrence of embolic manifestations. Fortunately, the embolus was small. Embolization might have been avoided had the patient either complained of his pain or been questioned for it.

EDEMA—Occasionally edema of very slight extent, due to venous obstruction, may be noted on the dorsum of the foot or over the shin. When marked it is usually late, signifies extensive and complete plugging, and carries with it relatively less danger of embolization.

VEIN TENDERNES—Vein tenderness is the most important physical sign for early diagnosis before pulmonary embolization occurs. Routine daily examination of the lower extremities of all patients confined to bed, whether for surgical, traumatic, or medical states, is absolutely necessary. Its significance and evaluation will be all the simpler if started the first day the patient is confined to bed: gentle, deep, one-finger palpation perpendicularly to the axis of the vein investigated, over the entire extent of the femoral, internal saphenous, tibial and plantar veins, that is, inner groin, inner thigh, popliteal space, calf, preastragalar and plantar areas. This tenderness is not

over the periosteum, ligaments, or muscle, the latter being excluded by absence of tenderness on bilateral pressure over the muscle mass.

A man, aged 52, was operated upon for a perforated gangrenous appendix. The fever promptly subsided. On the eighth postoperative day he suddenly complained of pain in the left side of the chest anteriorly, was very dyspneic, cold sweat, but no cough, expectoration, or cyanosis. This was diagnosed as a coronary closure. The next morning he expectorated some blood tinged sputum, friction rub and rales were found in the left axilla, and marked tenderness was elicited over the left calf. Pain and edema of the lower extremities were absent. Oxygen tent and immobilization of the lower extremities were immediately instituted. Subsequently marked edema of the entire left leg appeared, confirming the diagnosis of pulmonary embolism from a thrombus in the left lower extremity.

A man, aged 50, was admitted with a seven-day history of influenza, one day loss of power in both legs and difficulty of urination. Examination revealed a pyknic habitus, hypersensitivity, paresis of both lower and right upper extremities. Tenderness in the right calf was attributed to his general condition, and his attendants diagnosed postinfluenzal myelitis. Several days later, while on a bedpan, he suddenly collapsed and died. Postmortem examination showed transverse myelitis and occlusion of the bifurcation of the pulmonary artery by a saddle thrombus which when uncoiled equalled the length of the right popliteal and femoral veins. The remnant of the thrombus was present in the right posterior tibial vein.

MINOR PULMONARY EMBOLI—Minor pulmonary emboli may thus give the first clue to a preexisting venous thrombosis. These individuals are in the same age group in which coronary artery disease is so frequent and differential diagnosis may at times be difficult. The sudden onset of chest pain may be the first indication of pulmonary artery obstruction, or the pain may be present in the upper abdomen or epigastrium, and when accompanied by nausea or vomiting or persistent belching, lead to an erroneous diagnosis of mesenteric vessel closure, intestinal obstruction, or subphrenic space infection.

The clinical features of pulmonary embolism vary with the size of the obstructed pulmonary artery, severity of preceding heart weakness, and passive congestion of the lungs. The onset of symptoms while usually sudden, may occasionally be insidious and of slow evolution. In the severest cases death may be instantaneous or within a few hours. Shock is attended by cold clammy sweat and extremities, pulselessness, anxious facies, and marked drop in systolic blood pressure. These cases are erroneously diagnosed as

coronary closure. Manifestations of heart failure may occur where death is delayed a few hours to days.

We are here especially concerned with the minor embolizations, in which event bland hemorrhagic infarction of the lung follows where there has been antecedent left heart weakness and passive congestion of the lungs. Detailed description of hemorrhagic infarction will not be attempted here. Pain in the chest varies in degree and location. It may be precordial, retrosternal, posterior, or in the shoulder. In the hyposensitive patient, pain may be replaced by palpitation, vertigo, weakness, anxiety, or sweat. Fleeting dyspnea may be the first sign of embolization. Cough is usually delayed several hours. Hemoptysis of bright red blood is significant, occurs in relatively few cases, may be very marked, and no other signs or symptoms may be present. Leukocytosis follows. Fever also occurs late; the rise is usually step-like reaching its maximum in a few days, and gradually falling, particularly with improvement of the circulation by the use of digitalis.

Too thorough a physical examination of the chest should not be attempted as there is great danger of further embolization by moving the patient about. The physical signs when present are due to bland hemorrhagic infarction and occur more frequently at the bases especially the right lower. Occasionally the infarcts are multiple and bilateral. Any atypical signs in the chest occurring one or two days after suggestive symptoms of pulmonary embolization are suspicious of infarction. Dullness may be marked and localized, fine râles, friction rub, markedly diminished breath sound, bronchial breathing, may each or all occur. Erroneous diagnoses of pleurisy or pneumonia are not uncommon. X-ray examination has not proven of great value and is dangerous because of the entailed motion to the patient, even with the use of a portable apparatus.

Neurological symptoms, such as sudden syncope after exertion, are suspicious and are due to the resulting cerebral anemia. These are much more frequent in the presence of cerebral arteriosclerosis usually associated with advanced age and hypertension. These cerebral symptoms may lead to an erroneous diagnosis of cerebral hemorrhage or embolism.

The prognosis of the individual embolic attack will therefore depend on the size of

the embolus, disintegration of the embolus, age of the patient, elasticity of the pulmonary arteries (in the young, allowing blood to pass the clot), and good heart action. It cannot be sufficiently stressed that the slightest suspicion of pulmonary embolism, no matter how small, warns of the possible danger of a later massive fatal attack and must not go unheeded.

The prevention of fatal pulmonary embolism requires not only the prevention and recognition of early venous thrombosis, but, once venous thrombosis has occurred, taking all precautions to avoid embolization, and once minor embolization has occurred, to leave no step unturned to avoid massive embolization. Factors favoring dislodgment of the venous thrombus are mechanical jarring, straining at stool, sudden sitting up, transportation, and bandaging or massage of the involved lower extremities. Other factors as yet little understood are the suction action of the right heart, venous pressure, changes in the thrombus itself, and changes in the vein wall, any of which may operate while the patient is lying quietly in bed or even sleeping.

We do not wish at this time to discuss the various preventive measures for thrombosis or embolism or treatment when these conditions occur, except to mention that once thrombosis has occurred, the greatest care of the bowels and in the use of the bedpan, as well as complete immobilization of the lower extremities by means of properly adjusted sand bags at their sides and over the knees and ankles are vital. We believe that surgeons should be thoroughly schooled in the technic of doing the modified Trendelenburg-Meyer operation for massive pulmonary embolization, having everything in readiness so as to operate at a moment's notice when it appears that the patient's condition without this operation is otherwise hopeless.

CONCLUSIONS

1. Fatal pulmonary embolism is most frequently caused by peripheral venous thrombosis of the lower extremities.

2. A certain type of individual is apparently constitutionally predisposed to this complication.

3. Allergic factors, as yet insufficiently understood, may play a rôle in the production of venous thrombosis.

4. Individuals confined to bed for any reason whatsoever should be daily ques-

tioned for pain and daily tested for tenderness of veins of the lower extremities, especially during the second week of their stay in bed.

5. Early diagnosis of venous thrombosis of the lower extremities should be followed by prompt and complete immobilization to prevent fatal embolization.

6. The presence of sudden chest symptoms or signs occurring in the predisposed individual should lead to immediate investigation for evidences of peripheral thrombosis, and proper precautions should be taken.

CASE REPORT

SUDDEN DEATH FOLLOWING THE THERAPEUTIC USE OF SODIUM SALICYLATE

NORMAN STRAUSS, M.D., F.A.C.P., JULIUS ROSENTHAL, M.D.,
and
MICHAEL A. NOCERO, M.D.

From the Medical and Pathological Departments of the Morrisania Hospital, New York City

Fatalities from the therapeutic use of sodium salicylate in rheumatic fever are so infrequent that we feel this case deserves to be recorded.

W. K., age 40, born in Greece, was admitted to Morrisania Hospital at 4 P. M. on April 24, 1934. His complaint was pain and migratory swelling of all joints which had lasted three months. There had been about one year and a half previously an attack of joint pains limited to the lower extremities and lasting only a week, but there was no record of childhood pains or repeated sore throats. There had been no venereal disease. Six weeks prior to onset of the present illness he had a stubborn "cold" and cough.

Examination showed temperature 100.4° F., pulse 112, respiration 24. Pupils were miotic but reacted to light and accommodation. The tongue was coated, the teeth were in poor condition, the pharynx was markedly reddened, there was a postnasal drip, all the joints were red, swollen, warm, tender, and painful on motion. The right ankle and shoulders seemed most acutely involved. Both tonsils were reddened and enlarged, but no pus could be expressed. The heart gave no signs of rheumatic involvement. The lungs were clear, the abdomen negative except for appendectomy scar.

Diagnosis.—The patient appeared to have typical rheumatic fever with an upper respiratory infection.

Treatment included rest in bed, application of methyl salicylate and cotton to joints, a cradle with electric light bulbs over lower extremities, a single dose of 20 gr. each of sodium salicylate and sodium bicarbonate was given on admission.

Course.—At 10:30 A.M. the next day, 4-25-34, following a cleansing enema 120 gr.

of sodium salicylate in starch water was given rectally. No untoward effect from this dose was seen; in fact, the man said that he felt better.

At 6:30 P.M. a second dose of 120 gr. of sodium salicylate was administered per rectum.

That evening the patient vomited. He was given 30 gr. of sodium bicarbonate. He slept well that night.

At 6:00 A.M. next day, 4-26-34, he complained of nausea, tinnitus, and then became aphonic and perspired profusely. At 10 A.M. he was markedly prostrated, unable to talk, semi-comatose. He was given an enema in the effort to wash out any unabsorbed salicylate. Adrenalin, 15 minims, q. hy, was given. At 3 P.M. he went into acute collapse and expired at 3:12 P.M. despite intranasal oxygen, coramine, and alpha lobelin injections.

Postmortem Findings.—The general appearance of the body is that of a well-built middle-aged man. No abnormalities of skin or joints externally and no edema.

Scalp, skull and dura show no abnormalities. The subarachnoid space contains a normal quantity of free fluid. On section of the brain, there are no hemorrhages or areas of softening.

There is no free fluid in either pleural cavity. There are a few band-like adhesions at the base. Scattered throughout both lungs there are subpleural hemorrhages of varying sizes which on section are seen to extend into the lung parenchyma for varying distances. The lungs themselves are moderately congested; show no evidence of consolidation. The pulmonary arteries show no evidences of embolization.

The heart was apparently not enlarged; its weight was 320 gm., its contours were normal. The pericardial cavity contained about 75 c.c. of straw-colored fluid. The

parietal pericardium showed no abnormalities. The visceral pericardium showed a few small hemorrhages, located mainly on the posterior aspect of the right ventricle. The right auricle was somewhat dilated. The left auricle was of usual size. The myocardium was of a brown color. There were no scars, no infarcts, and no nodules of any kind seen. In the septum, just beneath the endocardium and below the middle cusp of the aortic valve, there could be seen an area of ecchymosis about 1.5 cm. in diameter. The valves showed no evidence of previous disease. Careful examination of the mitral valve, particularly, did not reveal any evidence of previous or existing pathology.

In the liver there were a few small hemorrhages under the capsule. There was congestion of the sinusoids. The parenchyma was pale. The gallbladder was normal.

The spleen was enlarged; its weight was 350 gm.; its color was deep purple. At the upper pole could be seen a small area of hemorrhage.

The kidneys were acutely congested. No hemorrhages or infarcts were seen. The pancreas and adrenals were normal.

The stomach showed a hemorrhagic gastritis with numerous submucous petechiae. Rectum and colon were negative.

Bladder and prostate were normal.

Anatomical Diagnosis.—Subserous hemorrhages of lungs, heart, and kidneys, hemorrhage into spleen, subendocardial hemorrhage, hemorrhagic gastritis, mild parenchymatous degeneration of kidneys and liver.

Chemical Findings.—Chemical examination of kidneys and liver showed these organs to contain a large amount of salicylates. Examination of the heart muscle proved unsatisfactory.

COMMENT

One of us (Strauss) has had a large experience with the use of this drug in the treatment of rheumatic fever with the following technic: After a low cleansing enema, 120 gr. of sodium salicylate in starch water is given twice a day for the first day; 60

gr. twice a day the second day, and 30 gr. twice a day the third day, a total of 240 gr. on the first day, 360 in two days, 420 in three days. Almost dramatic results follow, symptoms subside abruptly, swelling of the joints diminishes, pain on motion disappears, and the temperature drops to normal.

Heyn² published his experiences with 122 cases of rectal administration of sodium salicylate with equally good results. He states the adult dose consists of 8 to 10 gm. (120 to 150 gr.) of sodium salicylate dissolved in 120 to 180 c.c. of starch water.

In 1927, Hanzlick¹ said: "In general it may be said that the fatal dose of sodium salicylate is from 1 to 1.5 gm. per kilogram for all species irrespective of the method of administration; the fatal dose of sodium salicylate in man is not definitely known, but may be somewhat less than, or about 1 gm. per kilo."

Our patient weighed about 50 kilograms. According to this calculation our dosage was well within the margin of safety as our patient only received 17.4 gm. (260 gr.) in 36 hours.

This patient did not die an allergic death. He died as a result of the toxic effect of sodium salicylate as evidenced by the clinical picture of (1) nausea, (2) vomiting, (3) cerebral changes (loss of speech), (4) profuse sweating, (5) collapse, (6) death, (7) the characteristic postmortem changes described. This clinical picture likewise has been described by other observers.

Our troubled souls are, fortunately, eased by Stedman who placed the word "idiosyncrasy" into the medical dictionary with the following definition: "A susceptibility, peculiar to the individual, to the action of certain drugs." This patient, we believe, died as a result of an idiosyncrasy to sodium salicylate.

NEW FRENCH HEALTH "RACKET"

Under French law a soldier who is declared by the army physicians to be in perfect health on arrival at the barracks and who later develops tuberculosis or other disease, is assumed to have contracted the disease during his military service, and is entitled not only to an immediate discharge from the army, but also to a pension for the rest of his life. As a result, says the Paris correspondent of the *A.M.A. Journal*, the recruits have reversed their tactics. Formerly it was common for some to simulate deafness, excessive myopia,

or dysentery in order to be relieved of military service. Since the enactment of the new law the reverse is true. Now the simulators seek to conceal any disease with which they are afflicted in order not to reveal it until after two examinations have been completed, so that their disease may be declared to be a consequence of military service and give them the right to a pension. The physicians take great precaution to detect all fraudulent practices, most of which are well known to them.

Dr. Bedell's Address in Peekskill

In his address before the First District Branch, Dr Arthur J Bedell, the President of the Society, spoke pertinent words. His address is published in full elsewhere in our columns.

Dr Bedell is to be commended for bringing into the open the tactics of the opponents of organized medicine. Too long has the profession been the target for everyone who had a hobby to ride, a theory to propagate, or a reform to endorse. Instead of squarely standing upon the issues raised, it seems that the technique requires that the profession must first be besmirched. Thus, for example are the tactics employed by the State Commissioner of Health who is advocating compulsory health insurance and to accomplish that end, sends out a letter to the mayors of ten cities and the supervisors of ten counties pointing to the high infant mortality in the districts in question. To a layman the implication, of course, is that the physician and health services in these communities are at fault. The fact that one cannot use such infant mortality figures as a yard stick to measure either medical or health agency efficiency is shown

by the Statistical Report of Infant Mortality for 1933 in 985 Cities of the United States, published by the American Child Health Association.

In an address last June before the Cornell University Medical College, Dr Parran, again prophesying the early advent of socialized medicine yielded to the impulse to make the wish father to the thought. He then asserted that fifty thousand persons in New York State die annually for lack of proper medical care. It is to be feared that he was then performing some statistical *leger de main* to lend support to his views. Individuals who attempt to cure cancer with rattlesnake oil or diphtheria with absent treatment or appendicitis with a diet of raw fruits and nuts, will die whether medicine is socialized or not. As for the small percentage of cases where physicians rendered improper treatment, there will not be one hundred per cent competence in any field of endeavor under any system. The element of error will persist in all activity while the race retains its human attributes. It is more apt to exist in medicine under the stultifying conditions imposed on the doctor by compulsory health insurance than under the competitive stimulus of private practice.

If, on the other hand, Dr Parran wishes to imply that thousands of people die annually in this state although they apply for medical care and are refused, then it appears that state medicine insofar as it already exists has failed to function properly.

The releases of the Milbank Foundation, instead of standing squarely upon the issues raised by their studies, announce speeches by Mr Kingsbury, with flings at the "reactionary" and "obstructionist" attitude of the organized profession.

Dr Bedell points out the injustice of this, and urges that we take our place as Master in the House of Medicine.

If we must discuss changes in medical practice, let us at least stick to the mooted questions raised. Guerilla warfare and sniping at the medical profession hardly create the proper atmosphere wherein profit can be derived from studied discussion.

The Old Doctor and the New

It seems a strange thing that the superbly equipped physician and surgeon of to-day should require any defense against the charge that he is not as good as the "old family doctor" of days gone by. Yet we find in *The Scotsman* a statement by Dr. William Robertson that the present-day medical student is better educated than his predecessor of thirty or forty years ago, but he is not a better healer! This would not be worth noticing, perhaps, if it were not for the fact that popular affection for the old-time medical man has glorified him into a legendary and mythical figure. He is regarded almost as a miracle worker.

It may be worth a few moments of our time to explore the change of feeling that made the old doctor a demi-god and makes the new doctor merely an everyday human being. In the first place, we must recognize that the change in the popular attitude toward disease has been little short of revolutionary. In our grandfather's day many thought of illness as a visitation of an inscrutable providence, and a doctor who could enter the sick-room, take the pulse and temperature, and tell what was wrong, as clearly having something of supernatural powers. If the patient died, it was the will of heaven; if he recovered, the doctor had snatched him from the jaws of death.

The doctor, too, was not surrounded with instruments for testing this and that, he did not resort to laboratory examinations and reports, he did not send the patient to various specialists or call them in for consultation. In short, he seemed to personify in himself all the medical wisdom of the ages, and his patients set him up on a pedestal where he still seems to look down with a benign smile at our more fussy, if more scientific, procedures of to-day. Popular sentiment, or sentimentality, failed to realize that the old physician often did not know what was wrong with the patient. The affection might be called "inflammation of the bowels," hot or cold applications might be prescribed, and the outcome left to the will of fate, the sick man's lucky stars, or the strength of his constitution.

Now the young doctor, instead of entering practice after graduation, spends years in hospital work and learns that disease is no such simple matter as the "old family doctor" thought. He knows he must face cases of great complexity and difficulty and must try to solve problems that his predecessor did not even know existed. Hence he inevitably approaches his cases with more humility and may have less air of authority than the doctor of former times.

Yet this very fact proves him the better doctor, the more thorough-going scientist and diagnostician. His reliance on instruments, laboratories, specialists, etc., may prove to old Mrs. A. that he "doesn't know everything," but it proves to every sensible person that he is marshaling the wisdom of all medical science in a way that was impossible a generation ago. Again, as pointed out by a western Professor of Surgery, Dr. Russell Best, the doctor's instruments are merely extensions of his natural powers of observation. The older physician would himself have welcomed the newer equipment.

The popular glorification of the old family doctor also takes another turn. This grand old character used to bring all his wisdom to the bedside for a dollar a visit, and some people are unable to see why the modern practitioner cannot do the same. The high cost of modern medical education and training, the expenses of equipping and maintaining an office, mean nothing to them. They can understand why a modern automobile costs more than a horse and buggy, why a radio costs more than a mouth-organ, why an electric refrigerator costs more than an ice-box, but they cannot see why modern medical science should cost any more than the old-time régime of pills and plasters.

There, perhaps, we have the reason why welfare agitators are able to play skillfully on this feeling and persuade so many that a political socialization of medicine will give them all the benefits of modern science at the same rate their grandfathers paid for the "old family doctor." Well, the "new family doctor" knows it is impossible. Someone must suffer. In the first analysis, no doubt, it will be the

doctor, but in the last analysis it will be the patient. Let us hope the country will wake up to this fact before it is too late.

The Origin of Criticism

The origin of much of the criticism against the present system of medical practice comes mostly from two groups, the so-called philanthropic foundations and the State Board of Health.

The State Board of Health would extend preventive medicine. No one objects to this, but after all preventive medicine is strictly limited to such prophylactics and other preventives of disease which medical science has won. No act of legislature can extend prevention and institute protective measures where none are known to exist.

The activities of the numerous non-medical foundation workers who with the great wealth behind them set out to make studies and then, to enhance their importance to their employers, become political protagonists for the general adoption by legislation of the results of their studies, are another source of criticism of the medical profession. It were as if any scientific worker in medicine instead of publishing his studies and results, were ever afterward to agitate for its adoption by the profession instead of letting "truth find its way," which it has a habit of doing.

Has it never struck anyone that there exists a total absence of complaint from

the public which next to the profession is the most concerned in the matters at stake? Neither the public, the lay press, nor widely scattered communities have registered any public protest. Instead of this we see interested foundations activating publicity, encouraging discussion, even soliciting meetings to stir up and arouse an apparently apathetic public and its press to urge change in medical practice.

In these strenuous times, all this has at last succeeded in bringing some medical groups into being, who, more concerned with the economic status of the underpaid doctor than anything else, are working to better his status, and to secure their end they would accept even health insurance or anything else that would give these physicians adequate incomes. With their point of view we can have no quarrel, but we can hardly take the same stand, for we are concerned first with the quality of service the public gets, and next with the ultimate destiny of the medical profession. Change per se is unopposed by us. To meet conditions as we know them, we are ready to study any plans or procedure which is rational and practical.

The ten-point program of the A.M.A. provides a sufficiently broad frame within which we can all work toward a solution, and the first step toward that solution is to understand the necessities of the situation. Unwarranted criticism of the profession is hardly a reason to open the discussion.

DR. HOLT'S BOOK NEARING A MILLION

A forty-year-old book that is still going strong is Dr. L. Emmett Holt's "Care and Feeding of Children," which has sold 800,000 copies and is now published in its fifteenth edition. It is figured that every copy is read by at least five mothers and discussed by twenty. How did it get this extraordinary distinction, asks Harry Hanson in his book column in the *New York World Telegram*. As he sees it, it was because Dr. Holt "discussed the care of children in the simplest terms so that every mother could understand it. Besides, he wrote advice that was meant to keep the child well. He did not alarm the mother with a parade of symptoms and a list of preposterous precautions. He did not tell

anecdotes of all the terrible cases he has observed as a physician. He took for granted that the young mother wanted to know how to feed, clothe, and train her infant and keep him healthy and gaining. And because he had a fund of simple words he put it into the English language, forgetting Latin, Greek, and the passwords of the doctor." Mr. Hanson writes entertainingly, but should remember that thousands of doctors are telling mothers every day how to care for their babies, without using Latin, Greek, or "passwords," or frightening them with "preposterous precautions" or "anecdotes of terrible cases." Book reviewers, too, sometimes have a patter that is almost alarming.

News

of Interest to the Profession

ADDRESS BY DR. JOHN WYCKOFF

Delivered at the Laying of the Cornerstone of the Baruch Laboratory at Saratoga Springs, on September 14, 1934

MR. GOVERNOR, MR. NOYES, MEMBERS OF THE COMMISSION, GUESTS, LADIES, AND GENTLEMEN:

It is an honor to have been requested to speak here to-day at the laying of the cornerstone of the Research Building of the Saratoga Springs. The very fact that the opening of a building for research is considered by the Commission an important occasion, at which the distinguished Governor of the State is present, is in itself an indication of the importance in which the search for the truth in the development of a great institution for the public health has been held by the Commission in its planning.

Viewing these buildings, the people should realize the wisdom of the Commission, appointed by the Governor and supported by the legislature, in seeking the best advice available. The quality of the aid which the Commission sought is beyond criticism. Dr. McClellan, the executive director, of unquestioned scientific attainment, was given the opportunity to increase his already wide experience in scientific institutions by making a particular study of research laboratories associated with health resorts in various parts of Europe. Professor Groedel, one of the great authorities in balneology, himself an investigator of note, was made the official consultant in the development of the enterprise, and the Commission with its consultants has constantly conferred with the leaders of scientific medicine in the universities and research institutions of the state and country. They have also sought advice in their problems from organized medicine, conferring from time to time with the officials of the state and county medical societies. What a happy thing it is to find a Commission and its executive officers who are eager for advice and who are competent to judge its value and then act upon it!

I know that the things that I have spoken of are all true, but I think it will not detract one whit from the credit which belongs to the various governors of the

state and the state legislatures, the various commissions and the advisors and assistants of the commissions, to say that we all know that none of this would have been accomplished if it had not been for two men. The first of these is Dr. Simon Baruch, the first American to study hydrotherapy scientifically, and for many years professor at Columbia University in New York. During his lifetime he did more than any other person in this country to place hydrotherapeutics in its proper place in the armamentarium of the physician. He always believed that in this country we were neglecting our great natural resources such as these here in Saratoga and his interest in Saratoga and the development of these resources never wavered.

The second is his son, Mr. Bernard Baruch, who was so impressed by the convictions of his father that he has never ceased in his efforts to make Saratoga Springs available to the people. Anything that one would say in appreciation of their work must fall short of its desserts. There might well be placed a tablet here with their names and the last part of the inscription which is found on the tomb of Sir Christopher Wren in St. Paul's, "Si monumentum requiras, circumspice," which translated is "If you require a monument, look about you."

CHRONIC ILLNESS

To understand the purpose and the value of an establishment such as is being developed here in Saratoga Springs one must have some idea of the fundamental problems of chronic illness. Chronic illnesses have certain general characteristics: *First:* Chronicity—they last a long time. Strictly speaking, many of them are incurable. *Second:* During their course by interfering with function they produce handicap and often suffering. *Third:* Quite often such conditions are not the direct cause of death. In many forms of chronic disease death is frequently due to intercurrent acute manifestations, some

times of the underlying disease but often to some other disease which, finding its victim in a state of lowered resistance as a result of the chronic process, interferes with recovery.

Though chronic disease frequently remains with the patient, its proper management and treatment often controls and nearly always slows the progress of the disease, and such treatment teaches the patient to accommodate himself to his physical limitations and to live a useful and happy existence without further injury. It also teaches him to increase the reserve of the handicapped functions. It makes clear to the patient the wisdom of utilizing fully such functions as have little or no handicap and reeducates him to get joy out of doing things which he can do rather than insisting on doing the things which he cannot do.

Now, why are waters such as we find here peculiarly useful in the treatment of chronic disease, in increasing the patient's reserve or ability to function? I think it is safe to say that this is chiefly due to the effect upon the distribution of the blood supply to the various organs of the body. That the waters have an immediate effect upon the circulation depending upon the salt and CO_2 content, the temperature at which given, and the length of time applied, there is no question. This may be objectively proved. That patients, after a course of such baths properly given, have the reserve power of certain organs increased cannot be doubted. We have therefore in these waters a therapeutic instrument which if properly used may be of great benefit to our people. That it may be available for proper use depends upon three groups of individuals: the owners, who, I am happy to say are the State; the community which has grown around the springs, namely, the people of the county and city of Saratoga; and the medical profession.

It would be difficult to overestimate what vision the State has shown during the past few years in the development of these natural resources. First, she has obtained control of them; second, through various commissions who have gone to the far places of the world, as well as to domestic authorities, she has studied and developed a plan; third, she is putting this plan into execution and we are here today to celebrate a part of the development. If the State will continue such a policy

we need have no fears for the future of the Saratoga Springs. Let us hope that future administrations and legislation will be as careful as those of the past few years have been to avoid the seeking of special privileges, keeping one thing steadily before them as a guide, the development of these natural resources so that they may be used by all the people for their most important purpose, the prevention and alleviation of chronic disease. Because the reservation is beautiful, it would make a charming picnic ground, but at what a cost. Its use as a cure park would be gone for ever. Let us hope that in its development the State may never be tempted to allow its use for purposes other than rest and quiet. Let us hope that automobiles may remain excluded, and that nothing be allowed to enter which would in any way annoy the sick and tired who come to it as a haven. Is it too much to hope that there may be a few acres in this great state without hot dog stands, gasoline stations, or billboards?

If this great instrument for the treatment of disease is to be used to its fullest extent by all the people, the citizens of Saratoga also have a responsibility, a responsibility which I believe they have never fully met. The village, now so attractive to those who are well, must be made equally attractive to people who need rest and quiet. Facilities for the housing, feeding, and entertainment of tired people of various social backgrounds and financial capacities must be provided. Comfortable places to live should be provided where simple but excellent food, as prescribed by the physician, may be obtained, affording a reasonable profit. The Saratoga cure will not attract people for a single month as does the racing. It is quite understandable that with a short season, such as the racing season, prices have to be high. While the cure will unquestionably be seasonable, the season will be long, I should think seven or eight months, and when there are proper facilities for patients of various incomes and cultures, many will come here throughout the year.

If the citizens of Saratoga and New York State have been lethargic in their interest in Saratoga Springs, what is to be said of the medical profession? I do not speak particularly of the profession as represented in Saratoga County. In fact, these doctors have been interested and have made it possible for many to

receive the benefits of the waters under competent direction. On the other hand, the profession as a whole has been lethargic. There are several explanations for this. The first is a rather general lack of interest by the profession in the patient with a chronic disease; then the fact that we as a profession tend to pay more attention to technics associated with rapid cures than to those in which prolonged attention enables the patient to develop such resources as are left to him. Furthermore, we still think of preventive medicine chiefly in respect to infectious disease because of the phenomenal advances which have been made in applied bacteriology. Then, too, there is the question of a technic, if we consider the spa with its waters, bath houses, diagnostic institute, and cure park as an instrument, a large instrument, very delicate and quite complicated. To use it properly to the best advantage of the patient the physician must develop this technic. With the instrument as incomplete as it has been in the past it is natural that few physicians had the temerity to master the technic with an uncompleted tool. It is also natural that the best results could hardly be expected from the use of such an imperfect instrument. It does not, however, excuse the general lack of interest on the part of the profession in the development of these resources. But now that in Saratoga Springs we are having this great opportunity, the medical profession of the State has very real responsibilities. Like any surgical instrument, this cure, if used by men ignorant of its technics, may do harm. At present there are only a very few who can be said to have a good knowledge of it. The profession and the

State should encourage here a school for the study of the use of the spa in the treatment of such chronic diseases as may be prevented and helped by its use.

In addition, there will be presented an unrivalled opportunity in this institution, which I think it is fair to say has never been equalled, to study the nature of certain chronic diseases. Here the State is going to make it possible to study under ideal conditions certain phases of chronic disease of which so little is known. This opportunity can only be grasped to its fullest if the profession of medicine cooperates.

In sending patients to the spa for treatment there should be some way for the outside physician to know who is qualified to prescribe the cure. Certainly, every licensed physician is not so qualified and the indiscriminate use of such facilities as are being developed here with no medical advice or improper medical advice could not but help to bring even this great spa into disrepute.

Briefly I have tried to show that much has been accomplished and, we are glad to say, with vision. If the greatest good is to come out of this endeavor it must come as a joint effort of the state backing its commission, the people of Saratoga Springs and the medical profession. We have every reason from what we see here to-day to believe that such cooperation will continue and become even more coordinated. The result will be that people from our state, our country and from other countries will come here to lie down in green pastures with living but not still waters and so restore not only their souls but also their bodies.

ANNUAL MEETING OF THE FIFTH DISTRICT BRANCH

On October 2 the Fifth District Branch convened at Syracuse. Two hundred and forty-six physicians from the counties of Herkimer, Jefferson, Lewis, Madison, Oneida, Onondaga, and Oswego attended.

At the morning session Dr. Charles D. Post of Syracuse, President of the Onondaga County Medical Society, gave an address of welcome.

Two scientific presentations followed: *The Vagaries of Appendicitis*, by Frederic H. Flaherty, M.D., Syracuse. Discussion was opened by Hyzer W. Jones, M.D., Utica, and there followed considerable general discussion by both medical men and surgeons. *The Diagnosis and Treatment of Amebiasis*, by Thomas T. Mackie, M.D., New York. An

interesting discussion on this practical paper was given by Col. Robert H. Pierson, M.C., U.S.A. (retired), of Fayetteville.

The President of the Medical Society of the State of New York then gave an address in which he particularly stressed the work of the Society to help its members to improve their professional equipment and also spoke of the application of the TERA to the individual practitioner.

At the afternoon session the following papers were read: *The Rôle of Lead and Arsenic in Diseases of the Nervous System*, by Leon P. Cornwall, M.D., New York. The discussion was opened by Robert K. Brewer, M.D., Syracuse.

The paper provoked much interest because

it brought out much that is generally overlooked in the diagnosis of obscure cases and because in various industries there are hazards of chemical poisoning. *Pregnancy in Diabetics*, by Elliott P. Joslin, M.D., Boston, Mass. (by invitation). Dr. Joslin received a real tribute when all the members present stood after a graceful introduction by Dr. Groat. *Psychiatry and the General Practitioner*, by Mortimer W. Ryner, M.D., Medical Director, Bloomingdale Hospital, White Plains. Because this paper required for presentation more time than was available, it was cut short before completion. It will appear in full in the JOURNAL.

At the Evening Session there was set an unusually interesting symposium on *The Importance of Vitamins in Foodstuffs*. Frederick F. Tisdall, M.D., of Toronto, Canada, read the formal paper, and discussion followed by Brewster C. Douse, M.D., as to pediatrics, Raymond J. Pieri, M.D., as to obstetrics, and George P. Schafer, D.D.S., as

to dentistry. The paper and the discussion produced great interest in the meeting, and because of the applications to all people, in the press.

At the Executive Meeting Dr. Groat presented his resignation as President of the Fifth District Branch in order to render valid, under the technicalities of the by-laws, his coming reelection by the Council, as chairman of Standing Committee on Scientific Work of the Medical Society of the State of New York. The resignation was accepted with real regret.

The officers for the ensuing year will thus become

President (acting) LeRoy F. Hollis, M.D., Laconia

Second Vice President Murry W. Gardner, M.D., Watertown

Secretary Fred C. Sabin, M.D., Little Falls

Treasurer Herman G. Germer, M.D., Canastota

ANNUAL MEETING OF THE SIXTH DISTRICT BRANCH

Under the chairmanship of its President, Dr. John E. Wattenberg of Cortland, the Branch held its annual meeting on September 26, 1934, at Cortland. Members and guests came from the Counties of Broome, Chenango, Chemung, Cortland, Delaware, Otsego, Schuyler, Tompkins and Tioga.

At the morning session the following subjects were presented:

Address of Welcome by William A. Wall, M.D., Cortland, President, Cortland County Medical Society

Syphilis of the Central Nervous System by Hugh S. Gregory, M.D., Binghamton. Discussion by Eugene E. Bauer, M.D., Oswego, Orin Q. Flint, M.D., Delhi, and Stuart Piper, M.D., Elmira.

Traumatic Surgery: Essentials to Prevention and Cure of Disabilities, by Martin B. Tinker, M.D., Ithaca. Discussion by Harry Fish, M.D., Waverly, and Thomas F. Manley, M.D., Norwich.

Treatment of Pneumonia, by Russell L. Cecil, M.D., New York City. Discussion by Clifton H. Berlinghof, M.D., Binghamton, and Allen W. Holmes, M.D., Watkins Glen.

Surgical Managements of Carcinoma of the Rectum and Rectosigmoid, motion pictures, by Claude F. Dixon, M.D., Mayo

Clinic, Rochester, Minn. Discussion by Guy S. Carpenter, M.D., Waverly, and Ross G. Loop, M.C., Elmira.

During luncheon, Dr. Arthur J. Bedell, of Albany, as President of the Medical Society of the State of New York, spoke on the subject of *The New York State Journal of Medicine*.

In the afternoon the scientific session was resumed with the following subjects and speakers:

The Tragedy of Appendicitis, by Donald Guthrie, M.D., Sayre, Pa., President, Pennsylvania State Medical Society. Discussion by Arthur W. Booth, M.D., Elmira, James Greenough, M.D., Oneonta.

Treatment of Bacterial Endocarditis, by Ronald L. Hamilton, M.D., Sayre, Pa. Discussion by George Mackenzie, M.D., Coopers-town, Norman Moore, M.D., Ithaca.

Intestinal Obstruction, by William D. Johnson, M.D., Batavia. Discussion by Dwight G. Dudley, M.D., Endicott, William H. Hobbs, M.D., Binghamton, and Frank J. McCormick, M.C., Ithaca.

The Technic of Obstetrical Forceps, by William T. Getman, M.D., Buffalo. Discussion by Herbert W. Fudge, M.D., Elmira, and John W. Judd, M.D., Ithaca.

ANNUAL MEETING OF THE SEVENTH DISTRICT BRANCH

At the Auburn Country Club on September 27, 1934, the Seventh District Branch convened in its annual meeting.

The morning session included the following papers:

Arthritis, by Russell L. Cecil, M.D., New York City. Discussion opened by Floyd R.

Wright, M.D., Clifton Springs Sanitarium.

Common and Unusual Heart Lesions, by Harrison S. Martland, M.D., Newark, N. J. Discussion opened by Floyd S. Winslow, M.D., Rochester.

After luncheon, the program proceeded

Address, by Arthur J. Bedell, M.D., President, Medical Society of the State of New York, Albany.

Management of Gastric Lesions, Peptic Ulcer, and Malignancy, by Frank H. Lahey,

M.D., Boston, Mass. Discussion opened by Alfred Armstrong, M.D., Canandaigua.

Recent Advances in Neurology, by Foster Kennedy, M.D., New York City. Discussion opened by Louis T. Waldo, M.D., Rochester.

ANNUAL MEETING OF THE EIGHTH DISTRICT BRANCH

On October 4, 1934, the Eighth District Branch of the Medical Society of the State of New York held its annual meeting at Jamestown. One hundred and forty-three physicians from the Counties of Alleghany, Cattaraugus, Chautauqua, Erie, Genesee, Niagara, Orleans, and Wyoming were present. The attendance was 142.

THE MORNING SESSION.—*The Successful Application of the Welfare Law*, by Joseph S. Lawrence, M.D., Executive Officer, Medical Society of the State of New York. *The Nondrainage Treatment of Peritonitis*, by George W. Cottis, M.D., F.A.C.S., Jamestown. Discussion was contributed by Dr.

Harry Trick, Buffalo; Dr. Herbert A. Smith, Buffalo; Dr. Wm. D. Johnson, Batavia. *The Development and Present Status of Neurosurgery*, by Wallace B. Hamby, M.D., Buffalo; *Gallbladder Disease*, by Malcolm H. V. Cameron, M.D., Canada, F.A.C.S., F.R.C.S., President, Toronto Academy of Medicine, Assistant Professor (ret.) Dept. of Surgery, University of Toronto.

When Dr. Wm. D. Johnson of Batavia was called upon to discuss Dr. Cameron's paper he said "that Dr. Cameron's talk had left such a pleasant impression with him that he did not want to disturb that impression by discussion."

FOURTH ANNUAL MEDICODENTAL JOINT MEETING IN GREATER NEW YORK

Under the auspices of the Better Dentistry meeting of Greater New York, the five County Medical Societies, and the two District Dental Societies will hold a joint scientific meeting on December 3, 1934, for the fourth time.

The object of this meeting is to call attention of the members of both professions to the close relationship existing between systemic and dental diseases and to stimulate more interest and greater cooperation between the practitioners in the care of their patients, to the end that the public shall receive better service.

While this meeting is local in the metropolitan area, the JOURNAL believes that the principle involved deserves wider application; therefore the full program is here presented:

Morning Session: 10 o'clock.

Report on questionnaires sent to the Medical and Dental Colleges in the United States and Canada, M. O. Magid, M.D.

Discussion: William J. Geis, M.D.

Afternoon Session: 2:30 o'clock.

The Burning Tongue. (a) Medical Aspect, Samuel Clement Burchell, M.D.; (b) Dental Aspect, Joseph Schroff, M.D., D.D.S.

Discussion: John Homer Cudmore, M.D., Henry J. Spencer, M.D., Herman Prinz, M.D., D.D.S., Daniel E. Ziskin, D.D.S.

Dermatological Manifestations of Oral Diseases and Oral Manifestations of Systemic Diseases, Isadore Rosen, M.D.

Discussion: George H. Lewis, M.D., H. J. Kauffer, D.D.S.

Evening Session: 8:30 o'clock.

New York Dental Centennial Celebration.

Transition in the Art and Science of Dentistry, Dr. Frank A. Casto, President, American Dental Association.

Importance of Focal Infection as Related to Health, Dr. E. C. Rosenow, Mayo Clinic.

MEDICAL BROADCASTS

Scheduled under the auspices of the Medical Information Bureau of the New York Academy of Medicine and the Medical Society of the County of New York from Station WABC, Columbia Broadcasting System:

Thursday, November 22, at 11:15 A. M., 15 minutes. Subject: "After the Diagnosis." Speaker: Dr. William Darrach, Chairman of

the Committee on the Grading of Nursing Schools.

Thursday, November 29, at 11:15 A. M., 15 minutes. Subject: "Value of the Christmas Seal." Speaker: Dr. I. Ogden Woodruff, President, New York Tuberculosis and Health Association.

RECORD-KEEPING IN TUB. SANATORIA

For the first time it is now possible for tuberculosis sanatoria to keep uniform and complete records of all material facts about their patients, available at all times for instant consultation. This important improvement in health bookkeeping is a result of two years' work done by a committee of the American Sanatorium Association, assisted in a secretarial capacity by members of the staff of the National Tuberculosis Association. The 23 new forms which have been prepared are obtainable from the Livingston Press, Livingston, N. Y.

Formerly it was often necessary, when information of a consecutive or cumulative nature was needed, to expend considerable time and effort to collect and arrange pertinent facts from records made at different times, and reposing in various forms which were kept primarily for other reasons than the one which might now be in mind. The new system has the added advantage in rendering available, as a matter of routine, facts which serve to satisfy statistical needs from a national viewpoint.

Some of the forms are merely improvements over existing ones; others make an original contribution. Among the latter are these pertaining, respectively, to (a) nose, throat, ear, eye, and teeth; (b) pneumothorax; (c) operations; (d) tuberculous empyema; (e) statistical summary on discharge.

Forms are numbered and designated, as follows:

1. History, 4 pages. 1A. History.
2. Examination.
3. Nose, throat, ear, and eye—teeth.
4. Physician's orders.
5. Nurse's record.
6. Weight chart.
7. Temperature, pulse, and respiration.
8. Laboratory examinations (sputum, etc.).
9. Laboratory examinations (blood, etc.).
10. X-ray.
11. Re-examination.
12. Pneumothorax.
13. Exercise chart.
14. Heliotherapy.
15. Prescription for physiotherapy.
16. Consultation.
17. Operations.
18. Tuberculous empyema.
19. Permission for autopsy.
20. Admissions—discharges.
21. Statistical summary on discharge.
22. Blank form (heading only).
23. File folder.

The Committee of the American Sanatorium Association which was appointed to prepare the forms comprised: Dr. Everett Morris, of Auberry, California, chairman; Dr. H. A. Pattison, Dr. Ernest B. Emerson, Dr. F. Maurice McPhedran, Dr. Harry J. Corper, Dr. C. C. Browning, and Dr. Walter J. Marceley.

The secretarial work was done under the supervision of Jessamine S. Whitney, statistician of the National Tuberculosis Association.

THE NEW LILLY RESEARCH LABORATORIES

More than a thousand investigators and research workers were present at the formal opening of the new Lilly Research Laboratories at Indianapolis, on October 11. The gathering of distinguished visitors representing many noted bodies and famous institutions in this and foreign countries as well, assembled in a mammoth tent erected for the occasion.

At the formal opening exercises, in the afternoon, Eli Lilly, head of the organization, presided. Mr. J. K. Lilly, chairman of the Board of Directors, was introduced and responded briefly on "Research in Manufacturing Pharmacy," from the time of his entrance in the organization in 1876 up to the present.

Following Mr. Lilly's remarks, Dr. Irving Langmuir, Director of Research for the General

Electric Company, discussed "The Unpredictable Results of Research."

The chairman then introduced Sir Frederick Banting, who talked on "The Early History of Insulin." He gave an account of the early experiments conducted by Dr. Best and himself which first demonstrated the existence of insulin, and expressed his great appreciation of the cooperation which he and his associates had received from the staff of the Lilly Research Laboratories in the development of a practical, large-scale procedure for the production of insulin.

Sir Henry Dale, Director of the National Institute for Medical Research, London, and Secretary of the Royal Society, was the last speaker on the afternoon program. He chose as his topic "Chemical Ideas in Medicine and Biology."

MORE ABOUT MEDICINE IN CHINA

Another story showing that "the heathen Chinese is peculiar" in medical matters is told in a new book called "Medicine Man in China," reviewed in the *Bronx County Medical Bulletin*. This account of a young Chinese army captain, who had been wounded during a revolution, illustrates the natives' ignorance and distrust of surgery. The bullet had entered the abdomen and perforated the intestines. The youth's father, not realizing the extent of the internal injury, could not see the necessity of an opera-

tion for such a small external wound. Finally, after the patient complained that the bullet was moving around in his stomach, the father consented to its removal. The operation was performed and proved very successful. Several days later when the father saw the large operative wound, his indignation rose to great heights and he sent the doctor a bill for damages claiming that as a result of the operation his son's wound was much larger than it had been originally.

Medicolegal

LORENZ J. BROSNAN, ESQ.

Counsel, Medical Society of the State of New York

Civil Liability of an Unlicensed Practitioner

A few years ago a case was submitted for decision to our Court of Appeals involving the civil liability of a chiropractor for alleged negligence. The plaintiff, a woman, charged that she had employed the defendant to give her chiropractic treatment, and that after receiving nine treatments she became paralyzed as a direct consequence of the negligent acts of the chiropractor. She also charged that in treating her, the defendant was engaged in the practice of medicine in violation of the statutes in such cases made and provided.

At the trial, the plaintiff gave testimony in regard to the manner in which she was treated, and supplemented this evidence by proof that the treatment was not in accordance with recognized theories of practice, and that it produced the injury which followed, and further that a person qualified to treat disease should have foreseen that the treatment might have such a result.

She obtained a verdict in the Trial Court in the sum of \$10,000, which was unanimously affirmed by the Appellate Division. The defendant then appealed to the Court of Appeals, claiming that the Trial Court was in error in charging the jury that the fact that the defendant was practicing medicine in violation of the law could not be considered by them as some evidence of negligence. The Court of Appeals, by a divided Court, held that the Trial Court erred in thus charging the jury, and reversed the judgment and sent the case back for a new trial. The basis for the reversal is stated in the following language in the majority opinion:

"Evidence of defendant's training, learning and skill and the method he used in giving the treatment was produced at the trial and upon such evidence the jury could base finding either of care or negligence, but the absence of a license does not seem to strengthen inference that might be drawn from such evidence, and *a fortiori* would not alone be a basis for such inference. Breach or neglect of duty imposed by statute or ordinance may be evidence of negligence only if there is logical connection between the proven neglect of statutory duty and the alleged negligence."

There was a vigorous dissenting opinion by Judge Crane, in which he pointed out that

to adopt the view set forth in the majority opinion would practically place the chiropractor on the same plane with a duly licensed physician so far as the rules of civil liability were concerned. He said:

"The prohibition against practicing medicine without a license was for the very purpose of protecting the public from just what happened in this case. The violation of this statute has been the direct and proximate cause of the injury. The courts will not determine in face of this statute whether a faith healer, a patent medicine man, a chiropractor, or any other class of practitioner acted according to the standards of his own school, or according to the standards of a duly licensed physician. The law, to insure against ignorance and carelessness, has laid down a rule to be followed, namely, examinations to test qualifications, and a license to practice. If a man, in violation of this statute, takes his chances in trying to cure disease, and his acts result directly in injury, he should not complain if the law, in a suit for damages, says that his violation of the statute is some evidence of his incapacity. . . .

"The Public Health Law was intended to guard individual members of the public from the injuries which might result from resorting to unexamined practitioners. The violation of the law in this case has brought about the very thing which the Legislature has tried to prevent. In *Dent v. West Virginia* (129 U. S. 114, 122) the United States Supreme Court said regarding these Public Health Laws:

"Few professions require more careful preparation by one who seeks to enter it than that of medicine. It has to deal with all those subtle and mysterious influences upon which health and life depend, and requires not only a knowledge of the properties of vegetable and mineral substances, but of the human body in all its complicated parts, and their relation to each other, as well as their influence upon the mind. The physician must be able to detect readily the presence of disease, and prescribe appropriate remedies for its removal. Every one may have occasion to consult him, but comparatively few can judge of the qualifications of learning and skill which he possesses. Reliance must be placed upon the assurance given by his license, issued by an authority competent to judge in that respect, that he possesses the requisite qualifications. Due consideration, therefore, for the protection of society may well induce the State to exclude from practice those who have not such a license, or who are found upon examination not to be fully qualified."

"These words seem quite appropriate to our present Public Health Law. The defendant held himself out as a doctor, able to cure laryngitis. He had an office where his name appeared, as though he were a duly licensed physician. The plaintiff could not tell whether or not the doctor

was licensed according to the Health Law; she was not obliged to look up the records before going to him; nor was she expected to understand all the requirements of the Regents. She was one of that public which the law sought to protect by declaring that the so-called doctor was forbidden to do the very thing he did do, and which resulted in injury. . . .

"I am convinced that the plaintiff in this case was a part of that public for whose benefit the Public Health Law in this particular was passed. It was to prevent injury to such as she that the Legislature forbade the unlicensed practice of medicine. The plaintiff was injured through the defendant's disobedience of the law. He was treating her for laryngitis by pushing her vertebra. In pushing her vertebra and twisting her head, that is, by doing the very thing the law said he must not do, he caused paralysis. Thus by these authorities, the plaintiff could prove in connection with his acts that he was practicing medicine without a license, and such violation was, to say the least, some evidence of negligence. This is as far as the trial judge went in charging the jury. Personally, I am of the opinion that where an injury is the direct and proximate result of practicing medicine without a license, a recovery can be had, as for an act negligent *per se*; but we do not need to go so far in this case."

Despite the unanswerable arguments advanced by Judge Crane in his dissenting opinion, the law of the case was of course as set forth in the majority opinion, namely, that the admitted fact that the defendant was practicing medicine without a license and thus violating the law could not be considered by the jury as any evidence of negligence, unless the plaintiff could directly connect the violation of the law by the defendant with the injury complained of.

To remedy the legal situation here considered as a result of this decision, the Legislature enacted a statute (Section 1263, paragraph 6 of the Education Law), which provides as follows:

"In any action for damages for personal injuries or death against a person not licensed hereunder for any act or acts constituting the practice of medicine as herein defined, when such act or acts were a competent producing proximate or contributing cause of such injuries or death, the fact that such person practiced medicine as herein defined without being duly licensed shall be deemed *prima facie* evidence of negligence."

This statute lays down the rule contended for by Judge Crane in his dissenting opinion and, in the judgment of your Counsel, is a wise and salutary piece of legislation. A man who practices medicine without a license should not be heard to complain if the jury, in a civil action

against him for negligence, takes that fact into consideration in determining his liability.

Death of Patient Following Cholecystectomy

A woman about forty years of age entered a large public hospital on the gynecological service as a ward patient. A physical examination disclosed a complete descent of the uterus, flattened perineum, moderate rectocele and cystocele attendant upon complete prolapse, uterus retroverted and about normal in size, adnexae not palpable; also in the right upper quadrant there was a globular mass about four fingers below the costal border which was quite tender. The patient gave a history that for the past two years she had a feeling of a prolapse, and difficulty in moving the bowels and sometimes had blood in her stools.

While the patient was on the gynecological service she had a gallbladder attack, and the head of the surgical service was called in to examine her, and she was also examined by another doctor associated with the surgical service. The examination resulted in the diagnosis that the patient was suffering from chronic cholecystitis and cholelithiasis. The chief surgeon recommended an operation, to which the woman assented, and the other surgeon undertook to perform cholecystectomy and appendectomy.

Typical cholecystectomy was performed. The doctor found the gallbladder markedly enlarged and removed it, and found it contained a stone about the size of an egg. He also removed her appendix. While the abdomen was open he examined her liver, pancreas, stomach, duodenum, and common bile duct. These organs were normal, but the surgeon found an anomalous course of cystic artery, which looped behind and below the cystic duct. The doctor closed the wound, leaving a cigarette drain.

The patient's immediate postoperative condition was normal. However, the following night the woman became acutely ill with a high temperature. The surgeon

examined her and found tenderness along the right half of the abdomen and leakage of bile.

Upon removal of the cigarette drain it was discovered that bile was flowing freely, but there were no indications of bleeding. The doctor ordered continuous intravenous gastric lavage and morphine. Her condition continued to become worse, and diagnosis was made of an infection beneath the liver, and a quantity of light brown bile-stained pus was withdrawn by aspiration, which upon examination revealed a very virulent type of bacillus infection. Consultation was had and an operation was performed for incision and drainage of subphrenic and subhepatic collection. The patient, however, did not regain consciousness after the operation, and died a few hours later, the cause of death being given as chronic cholecystitis and cholelithiasis, contributory acute peritonitis postoperative.

The husband of the patient sometime later was appointed administrator of the deceased and instituted an action against the surgeon who performed the first operation, charging him with causing the death of his wife by reason of his negligence in performing the operation, and further charging that the operation performed by him had not been consented to. The case came on for trial before a Judge sitting without a jury, and the only witnesses who testified on behalf of the plaintiff were the husband and the sister of the deceased. The principal contention which the plaintiff made upon the trial was that the operation had been performed without consent given directly to the defendant doctor, which had been conceded by the defendant in advance of the trial. The Court dismissed the complaint at the close of the testimony put in on behalf of the plaintiff without requiring the defendant to put in a defense, and ruled that the plaintiff had failed to establish that the defendant's operation constituted an assault. There was no proof of any kind that the treatment was negligently or improperly performed. An appeal was taken from the ruling of the Trial Court, which resulted in an unanimous affirmance of the judgment in favor of the doctor.

Treatment of Ischiorectal Abscess

A married man, thirty-nine years of age, consulted a doctor specializing in surgery with respect to a rectal condition and told the doctor that seven years before he had undergone an operation for rectal abscess, and that several months after the said operation a swelling had formed in the rectum, which caused a discharge, and that from time to time thereafter he had been troubled by a chronic discharge and swelling, and that he had been constantly troubled with constipation. The doctor examined him and found that he was suffering from a rectal fistula and recommended an operation. The doctor made a complete excision of the fistulous tract after opening it into the anal canal. The fistula was situated on the right side, the external opening being $\frac{1}{2}$ -inch from the anus and the inner opening about 1-inch from the orifice. He made two additional incisions for the purpose of dissecting out hemorrhoidal veins. The incision for the fistula was packed with gauze, and the incisions made for the removal of the hemorrhoidal veins were closed with interrupted silk. Patient remained in the hospital for two week after the operation, and at the end of that time he was discharged in very satisfactory condition. He returned for aftercare to the doctor's office about twice a week for some time, and every time he appeared his condition showed extreme neglect and failure to carry out the doctor's instructions with respect to cleanliness. About two months after the operation he failed to return for further care and went to another doctor who found an abscess on the opposite side of the rectum from the location of the fistula. The said doctor performed another operation upon him with respect to that condition.

The patient thereafter instituted a malpractice action in which he charged that the defendant in performing an operation upon him with respect to an ischiorectal abscess had performed the same negligently and had failed to keep the operative field clean and free from infection so that it was necessary for him to undergo another operation. He also claimed that as a result of the defendant's alleged negligence he had lost control of his bowels.

The case came on for trial before judge and jury and the plaintiff after telling his version of the treatment he had received

and the suffering which he claimed to have undergone failed to call any physicians to testify that anything the defendant did in the treatment of the case was improper. The court, therefore, at the conclusion of the testimony introduced on behalf of the plaintiff, granted the defendant's motion to dismiss the action without requiring the defendant to be put to his defense in the case, thereby successfully terminating the case in favor of the doctor.

Operative Treatment of Muscular Dystrophy

A boy, twelve years of age, was admitted to an orthopedic hospital for treatment as an advanced case of pseudohypertrophic muscular dystrophy with complete paralysis of the back and extremities, flexion deformities of the knees and hips, and acquired club-feet. The patient was almost totally disabled, being unable to walk, having a flexion deformity of both knees and hips. It was found that physiotherapy and manipulation of his limbs did not improve the patient's condition, and although he was a poor operative risk it was decided by the physicians in charge of the case that an operation should be performed upon the boy to overcome the flexion deformities. The patient was put under a gas-oxygen anesthesia and the flexion contractures of both knees were corrected by reverse-leverage method. The tarsal joints were vigorously stretched over a Thomas

block to correct the varus deformity and the Achilles tendon manipulated. A plaster-of-paris bandage was then applied from the groin to the toes with the knees hyperextended and the feet in neutral attitude as regards lateral position and in slight equinus. A preliminary examination for the operation had been made which indicated that the boy would be a safe subject for general anesthesia, but after the operation was completed he failed to come out of the anesthesia and went into shock. The surgeon who performed the operation gave him stimulants which improved his respiration but had no effect upon his circulatory system, and the patient expired within half an hour after the conclusion of the operation.

Subsequently an action was instituted by the administrator to recover damages, based upon allegations of wrongfully causing the boy's death against the surgeon in chief at the hospital. As a matter of fact, the doctor so named as defendant in the action did not perform the operation and was present only at the operation in the capacity of assistant. More than two years after the boy's death an attempt was made to bring in as party to the action the surgeon who actually performed the operation, but as to the second defendant the case was dismissed on showing that the action had not been brought timely against him. The plaintiff's attorney thereupon consented to discontinue the action as to both defendants.

COLORFUL HEALTH POINTERS

Dashes of color run through the radio talks given by the Jefferson County (Alabama) Board of Health, now bound in convenient volumes under the name, "Health by Radio." A startling title of one talk is "The Disgrace of Dying." It puts the blame for practically all deaths except those of old age squarely upon individuals or the community. The speaker declares that "everyone who dies from any other complaint than old age, dies prematurely from an 'unnatural' cause and in the vast majority of cases, a premature death is a preventible death, hence a disgraceful, because an unnecessary, death. The average death is a reflection on the intelligence of somebody, either the victim, his family, or the larger family, which is the community or society in which he lived. You may not believe this so permit me to elaborate somewhat."

Under the popular "Believe It or Not" challenge the listeners are invited to test their own

beliefs about certain widely held superstitions, fads, or half truths.

Some other good topics which approach public health from the point at which the listener's interest is the greatest, notes a reviewer in the *American Journal of Public Health*, are "How's Your Rheumatism?" "Wooden Indians" (about how ideas and knowledge have changed), and "Little Bugs and Big Bugs."

Trees laden with Forbidden Fruit will be one of the sights to greet the American globe trotters who visit the Seychelle Islands on the Franconia cruise. The Forbidden Fruit is the coco de mer, the "apple" that Adam and Eve were forbidden to eat. According to tradition, the Garden of Eden was located in Praslin, one of the Seychelle Islands.

Books

BOOKS RECEIVED

[Acknowledgment of all books received will be made in this column and this will be deemed by us a full equivalent to those sending them. A selection from this column will be made for review, as dictated by their merits, or in the interests of our readers.]

Industrial Maladies.—By Sir Thomas Legge, M.D. Edited by S. A. Henry, M.D. Octavo of 234 pages. New York and London, Oxford University Press, 1934.

Clinical Toxicology.—Modern Methods in the Diagnosis and Treatment of Poisoning. By Erich Leschke. Translated by C. P. Stewart, Ph.D., and O. Dorrer, Ph.D. 12mo. of 346 pages. Baltimore, William Wood & Company, 1934. Cloth, \$5.00. (The Gloucester Series.)

X-Ray and Radium Injuries.—Prevention and Treat-

ment. By Hector A. Colwell, Ph.D., and Sidney Russ, D.Sc. Octavo of 212 pages, illustrated. New York, Oxford University Press, 1934.

Mothers' Guide When Sickness Comes.—By Roger H. Dennett, M.D., and Edward T. Wilkes, M.D. Octavo of 400 pages. Garden City, N. Y., Doubleday, Doran & Company, 1934. Cloth, \$2.50.

Practical Talks on Heart Disease.—By George L. Carlisle, M.D. Octavo of 153 pages. Springfield, Ill. [c.1934]. Cloth, \$2.00.

BOOKS REVIEWED

International Clinics.—A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles on Treatment, Medicine, Surgery, etc. Vol. 1, 44th Series, 1934. Louis Hamman, M.D., Editor. Octavo of 320 pages, illustrated. Philadelphia, J. B. Lippincott Company [c.1934]. Cloth, \$3.00.

Some of the articles in the department of Medicine are on hepatic Insufficiency, Jaundice, Enlargement of the Heart, and Recent Advances in the Treatment of Cardiac and Renal Edema. In the latter article, Gorham and Crouse of Albany describe some patients treated by the method of Lashmet and of Barker. Lashmet (*J.A.M.A.*, Sept. 26, 1931) emphasized the importance of the reaction of the ash of the diet in the treatment of nephritic edema. He prescribed a diet of "neutral ash" with 10 to 15 gm. of ammonium chloride daily as an acid-producing salt. M. H. Barker (*J.A.M.A.*, June 18, 1932) published observations on "Edema as Influenced by a Low Ratio of Sodium to Potassium Intake." He substituted potassium for sodium chloride giving 5 gm. of potassium chloride daily with a diet producing an acid ash, 2,500 calories, and fluids not restricted. A combination of these methods was used and of 9 patients there were 2 failures, 3 partial responses and 4 highly satisfactory results.

One section of the book is devoted to surgery, one to pediatrics and there are very good reviews of recent progress in medicine and surgery.

There is a new feature which consists of clinical case studies of two patients, the reader attempting to make his own diagnosis on the data given which will be supplemented if requested by laboratory reports.

WILLIAM E. MCCOLLOM

A Text-Book of Pharmacology and Therapeutics.—By Arthur R. Cushny. Tenth Edition. Edited by C. W. Edmunds, M.D., and J. A. Gunn, M.D., Octavo of 786 pages, illustrated. Philadelphia, Lea & Febiger, 1934. Cloth, \$6.50.

The tenth edition of this standard work is fully up to the calibre of its predecessors. In it, new knowledge in many sections of pharmacology and therapeutics have been added, but the added material is strictly confined to facts and not to fancies. Matters of uncertainty are omitted. The section on vitamins is very informative and gives a clear picture of our knowledge of these substances.

The chemistry and pharmacology of the digitalis series are well explained. It is shown that digitalis is much more effective clinically in auricular fibrillation when the heart muscle is badly nourished and decompensated than in those cases of fibrillation in which the nutrition of the heart is good. In these, very little slowing may occur. The authors explain clearly the antagonism of the two actions of digitalis, the slowing of the rate through the inhibition mechanism and the increase in contraction and diminution in heart size due to direct action on heart muscle tone. In the normal heart this results in diminished cardiac output whereas in the mal-nourished decompensated heart it causes a decrease in heart size and a slower rate giving a greater cardiac output.

The latest revision of Cushny's work will keep it among the first rank of works on Pharmacology and Therapeutics.

EDWIN P. MAYNARD, JR.

Modern Clinical Syphilology.—By John H. Stokes, M.D. Second Edition. Octavo of 1400 pages, illustrated. Philadelphia, W. B. Saunders Company, 1934. Cloth, \$12.00.

The revised edition comprises some thirteen hundred pages and represents, in the opinion of the reviewer, one of the most complete single-volume works on any given subject. The work is remarkably comprehensive on clinical syphilology from any standpoint. Many of Stokes' text summaries and thumbnail résumés, a feature of the first edition, have been added. The work has been extended to include a survey of the world literature. Numerous new illustrations are included. The author has, in addition, embraced material based on seventy-five thousand case records in this country under the organized efforts of the U. S. Public Health Service and five leading university clinics.

Whether one is a general practitioner or specialist in any branch, he would do well to possess this book for ready reference. The reviewer cannot say enough to express the manner in which he has been impressed with the results of the efforts of an outstanding leader and the respect and admiration he holds for his talent and industry.

AUGUSTUS HARRIS

Obstetric Medicine.—The Diagnosis and Management of the Commoner Diseases in Relation to Pregnancy. Edited by Fred L. Adair, M.D., and Edward J. Stieglitz, M.D. Octavo of 743 pages, illustrated. Philadelphia, Lea & Febiger, 1934. Cloth, \$8.00.

Here the internist and obstetrician have collaborated in an effort to manage their common problems. A perusal of this volume leaves the reader well satisfied with the results obtained. It is medicine considered from the standpoint of obstetrics and obstetrics considered from the standpoint of medicine.

Personal viewpoints which are of so much value, are expressed by a reputable list of contributors and the subject matter is thoroughly covered by men of experience in the various fields. Especially to be noted for its thoroughness is the section on infectious diseases, and in this section the chapters on Syphilis and on Venereal Diseases offer the reader some very practical points for consideration.

The authors are to be complimented for compiling a work of such a comprehensive nature.

WILLIAM C. MEAGHER

Spinal Anesthesia.—Technic and Clinical Application. By George R. Vehrs, M.D. Octavo of 269 pages, illustrated. St. Louis, C. V. Mosby Company, 1934. Cloth, \$5.50.

This is a thorough review of the development and stages that the method of producing spinal anesthesia has gone through. The book is very well illustrated and has an abundance of references.

Considerable space is rightfully given to physiology. There is a chapter on heart and respiration, also a chapter on circulatory and metabolic factors occurring during spinal anesthesia.

A description of the physiochemical action of novocaine in its fixation with nerve tissue is given.

W. G. FLICKINGER

The Essentials of Physical Diagnosis.—By Robert W. Buck, M.D. Octavo of 259 pages, illustrated. Philadelphia, W. B. Saunders Company, 1934. Cloth, \$3.00.

This volume is a practical exposition of physical diagnosis. Principles and methods are clearly presented and discussed. The interpretation and significance of physical signs are intelligently dealt with. It is the type of book for which there is a present-day need, and the student and practitioner will be amply rewarded by a study of its contents.

HENRY JOACHIM

PREPARED PHYSICIANS

An Address Delivered at the Meeting of the Second District Branch by the President

ARTHUR J BEDELL M D

Albany

It is with some diffidence that I address you on Prepared Physicians because there must be reference to control and most of us are weary and dismayed when we look about and see the effects of codification, regulation and regimentation. The subject of preparedness is too large to be considered in all of its phases this evening, but the two major and basic fundamentals, technical skill and ethical relationships are sufficiently interesting to hold our attention.

The present method of training physicians is woefully wasteful of time and energy, as well as money. We all admit that a physician should be ready to start practice before he is 27 or 30 years old. The long term of preparation dulls his youthful enthusiasm, suppresses his early impulses to progress, thereby reducing his initiative and productiveness. It is as Ruskin said of Turner's early life in school: "It carefully repressed his perception of truth, his capacity of invention and his tendencies of choice." He becomes too timid, his mental reactions are inhibited by a too prolonged period of apprenticeship and dependence. This almost invariably leads to a false sense of his value. Frequently he is a mere cog in an institutional mill where he adopts the life patterns of those about him, not that this is necessarily harmful for it may be most beneficial, but it is stifling to advancement both in the theory and practice of medicine.

After many years as an undergraduate and postgraduate teacher, I have reached the conclusion that the soundest, most practical and probably the best way to save time in the preparation of a physician is to con-

centrate on his preliminary work in high school and college so that he will be ready for medical school at least two years earlier than at present. The ideal medical course should be longer in actual months of training over a shorter number of years. There is no reason why the plan proposed by Davison for a year of forty-four weeks of medical college instruction should not be introduced and a year saved for clinical work. Most students spend their vacation periods in hospitals or laboratories. How much better to have them follow a regular curriculum and remain under academic control. If in this way three years are saved in preparation we can insist upon hospital training as a requisite for license. Few, if any, will object to this necessary finishing instruction where the student is given at least one year in which to correlate his medical facts and place them in practical working order. This plan would, I am sure, give us better prepared physicians.

There is no doubt that the wise physician continues to study throughout his entire life. He budgets his time for reading, for the stimulation resulting from medical society meetings, for the investigation of puzzling problems and the writing of essays. Unless these four are combined some side of his professional fullness of life will be neglected and he will in some way restrict his field of usefulness.

The prepared physician joins his county society and regularly attends its meetings. At first, he is instructed but soon assumes the role of instructor. He goes to his District Branch meetings to widen his horizon

of medical perspective. By active interest in the State Society he takes his logical place as a leader as soon as his skill is demonstrated, which may be by papers, by discussions, by scientific exhibits or participation in the post-graduate instruction courses. The State Society offers an open forum for the advancement of medical thought not only in these ways but also in its Journal. With your help our Journal can be made one of the most important reservoirs of current medical thought. To each and every one of our State activities I urge your attention and invite your active interest.

The American Medical Association meetings should be attended whenever possible. The addresses and scientific exhibits are the finest in the country and merit the careful consideration of all physicians. As one of your delegates to the American Medical Association, I ask your serious consideration of all phases of the American Medical Association activities.

The successful physician must be taught early in life that in the knowledge of health and sickness is the power to care for the well and cure the sick. He must have an inquiring disposition, a retentive memory, and an inherent and trained ability to use all of his special senses to become a wise counsellor.

The time has come when the public should be informed regarding the qualifications of those who claim to be specialists in any department of medicine. For many years there have been examining boards consisting of members appointed or elected from special societies to conduct the examination of applicants. The first board was that devoted to ophthalmology and since then several other departments have made their influence felt in this most practical way. Up to the present state boards have not licensed specialists.

We are living in an age when the established order has been subjected to a critical examination in the crucible of economic unrest, when those untrained by experience and unqualified by mental inaptness render opinions obviously incompetent on one side and biased on the other.

Surely it is a sorry state of affairs when things pertaining to the actual practice of medicine are left to those who have never had any contact with the sick except as statisticians and readers. When the rules of health of the state are promulgated by those not associated in any way with the

delivery of medical service it is time for organized medicine to rebel.

On the air and in the press the self-appointed parade back and forth on the stage of medical service, first in one role and then in another but always cast in fanciful forms against the present day methods of practice. It is high time that we, the organized profession of the State known to all as a most humane and honorable body protest against the activities of public servants preaching against us individually and collectively. Let us make a determined stand against all health agencies which capitalize illness and raise false standards of past and future achievements of medicine for their own advancement.

Let us break the chain of governmental usurpation of medical power which grew as an automatic process one step leading to another until either by design or by chance we have arrived at the place when for the good of the people of this country we must rend it, for once it is broken the pernicious life taking procedure will stop.

The rules for professional conduct are the basis of all our relationships with patients and physicians but morals begin with individuals and not societies. When the sense of right is once obtunded it always remains weakened. * Getting money under false pretenses, fee-splitting, almost always reduces the effectiveness of the recipient. Our regulations have been conceived and are enforced for the application of the all embracing golden rule to do unto others as you would have others do unto you. When everything seems to be going badly, when pinched by necessity and shrouded in the darkness of adversity, the tempter appears with a demand for an improper operation, an untrue witness statement, a false affidavit or a divided fee. Gentlemen, there is nothing which so destroys moral fiber and physical power as leading a dual existence. One cannot serve the god of medicine and the idol of ill gotten gain at the same time for inevitably the influence of the latter controls action. We know that there are very few moral delinquents in our ranks but those few bring discredit upon the entire group and they must either give up their evil ways or get out of the society.

We the organized profession of the state are vitally interested in anything which tends to reduce our efficiency, we frown upon minor infractions of our rules and grow righteously indignant when any one

dares to openly break our most protective regulations by blatantly advertising. Recently we have been chagrined and mortified by the experience of a man who attempted to elevate himself by publicizing a hospital.

If we follow these precepts we will indeed be prepared physicians not only to care for the sick and to prevent illness but also to withstand the attacks of those who wish to make physicians mere servants and the public weak supplicants.

It is as unethical for a hospital, clinic or dispensary to advertise as for an individual and when an institution does, then each and every medical member of it, is to my mind guilty, for he hopes to profit by such a display of physical plant or professional equipment.

Hospitals are false to their trust when they advertise an unknown, untried man as capable of doing a particular kind of work and without sufficient investigation force him upon the public. And this applies just as forcibly to medical colleges who blazon forth their superior advantages in the lay press.

Recently an old ghost has reappeared in a new garb. I refer to so-called medical reviews, advertising journals and drug house reprints. Most of these are unethical. Do not keep them alive by allowing your good work, your successes, to reach the profession through such channels but rather use your own State Journal.

The Workmen's Compensation Act is most unfairly managed. The State Insurance fund is so viciously and so maliciously conducted that organized medicine is forced to raise its voice in protest and demand a judicial investigation of some of its pernicious practices.

I know that underlings paid from taxes

collected from me deliberately try to destroy faith in my medical competency. I know that it is done in such an underhand fashion that carrier and physician are led to believe that my work is inferior. Gentlemen, most of you have experienced the same thing and most of you have suffered from whispering campaigns. Are you ready to show your force, make your demands and have your requests for fair play granted? If so, let us carry on in a most vigorous way with one objective, the best care for the injured. No more disparagement of known skill, no more reflections on ability but fair and square conduct by all concerned. If you are ready then let us carry your wishes to Albany this winter. Let us make this one of our major issues this year to the end that honor and reputation cannot be besmirched by paid hirelings. Let us clean house and remove the rascals high or low who stoop to such subterfuges and such deceits whether in our ranks or in those of the insurance carrier's.

Let us tonight reconsecrate ourselves to the cause of medicine and rally to the saving standards of our rules of professional conduct.

Upon each and every one rest these obligations. We cannot, we must not falter in either for if we do an overwhelming catastrophe will overtake the practice of medicine and the protection it gives the public. Our responsibilities are many, our opportunities numerous and our heritage of medical example too sacred to be denied.

I am strong in my faith and firm in my convictions that organized medicine through the individual will meet the high professional standard and ethical plane for which I hope and you desire.

344 STATE STREET

INSPIRATION A "REAL THING" IN MEDICINE

Inspiration is "a real thing" and "a necessary thing for the medical practitioner," and it is a poor medical school which cannot supply it, "either through its atmosphere or through the personality of one or more of its teachers," says Sir Henry Brackenbury, in the course of an article in the *British Medical Journal* on "The Training of the Medical Practitioner." He goes on to say that without it the student's acquirements will be imperfect and his work, both during his studentship and thereafter through his professional career, a burden, or at least a source of infinitely less satisfaction than it might other-

wise have been. If the student is not put in the way of acquiring, or of developing, some width of culture, a zest for knowledge, a love for his work, a real sympathy with human suffering and trouble, a profound respect for confidence reposed in him, an appreciation of nobility of character and of the dignity and peculiar requirements of professional life, to that extent will the contribution made by the medical school to his medical education have failed of its complete purpose, and to that extent will he pass out from it a liability rather than an asset to his profession and to the community.

EXPERIMENTAL EVALUATION OF THE USE OF SOME VAGINAL ANTISEPTICS DURING LABOR

A Preliminary Report

R. GORDON DOUGLAS, M.D., and HENRIETTA S. RHEES, M.S.

From the Department of Obstetrics and Gynecology, New York Hospital and Cornell Medical College, New York City.

Several decades ago strong and frequently irritating solutions were used in an attempt to sterilize the vagina during labor and also for the purpose of disinfecting the vagina and uterus during the puerperium. The ineffectiveness of the practice for both purposes soon brought the method into disrepute. In the last ten years there has been considerably more interest in the subject, especially in this country and in England, which has followed the demonstration of the importance of the vaginal secretion during labor, as a source of puerperal infection, and also the introduction of new antiseptics having very high bactericidal powers and a low degree of toxicity for mammalian tissues.

Mayes,⁷ Brown,² Bessesen,³ Chase,¹ Somerville,⁵ Strahlmann,⁶ and others, have published more or less enthusiastic reports of the improved clinical results obtained through the use of various antiseptics instilled in the vagina or applied by means of a tampon during labor. However, the evaluation of the bactericidal action of these antiseptics in the vagina *in vivo* has received but limited study. Mayes¹ investigated the bactericidal action of mercurochrome on the external genitalia, in the vagina and cervix, with convincing results of the value of 4 per cent aqueous mercurochrome as a vaginal antiseptic. However, he used only blood agar plates for media and all inoculums were streaked on the surface of the media and incubated only aerobically. In our estimation this method of examination is entirely inadequate when dealing with some slow-growing organisms and a flora which is often predominately anaerobic in the vagina during labor. In our experience the anaerobes play the preëminent rôle in puerperal infection, and it is not an uncommon experience to find patients with puerperal infection of a mild nature, or patients with quite severe types of infection, to have specimens of lochia obtained from the uterus which

produce no growth whatever when streaked on the surface of freshly prepared blood agar plates. While, on the other hand, when similarly prepared plates are cultured under anaerobic conditions often profuse growth is obtained.

For these reasons we were convinced at the onset of this work that it would be necessary to have duplicate specimens of the same inoculum cultured under both aerobic and anaerobic conditions. For the purpose of making certain that all viable organisms in our specimens were provided with facilities for growth, we further deemed it necessary that in the case of solid media, the inoculum should not be streaked on the surface of the plate, but should be actually in the media, such as is accomplished by the use of poured plates. This prevents the error involved in that some slow-growing organisms do not develop colonies sufficiently large for identification before the surface of the plate becomes dry. Our study to date is incomplete, covering only three antiseptics and comparing the bacteriological findings with those of a control series of patients. The work is being continued with other antiseptics and will be presented at a later date.

In our investigations we were not concerned whether the effect of the antiseptic was achieved more in one part of the vagina than in another, on the assumption that the ideal vaginal antiseptic must thoroughly disinfect the entire vagina and not only a portion of it. As an index of this effect we do not feel that one is justified in drawing conclusions by the division of organisms found, into pathogens and nonpathogens. In fact, except in rare instances one can question with considerable authority such a division of the vaginal flora. Accordingly, in evaluating the results of our experiments we have used as an index the total number

of viable organisms in the inoculum as demonstrated by colony counts

TECHNIC OF INSTILLATIONS AND OF TAKING CULTURES

The technic as outlined here, was evolved after several modifications in a preliminary series of experiments, and was gradually changed to its present form which seems to be satisfactory for the quantitative determination of the number of organisms in a unit of volume of vaginal secretion, at any given time during the first stage of labor.

Long applicators, 12 inches in length, with the same quantity of absorbent cotton wound tightly about the tip, sterilized in test tubes with dry heat, were used for taking cultures. The patient was placed on a bed-pan, the legs flexed and the knees widely abducted. Sterile gloves were put on the unscrubbed hands with aseptic technic. The thumb and index finger were placed between the labia majora and labia minora on either side, the vaginal orifice being brought into view by spreading the fingers. The applicator was then inserted in the vagina touching no part of the external genitalia, until it had passed beyond the hymeneal ring. With a rotary movement in the same direction the applicator was inserted up to the vault of the vagina, rotated about fifteen times and withdrawn, the labia being kept widely apart during the entire procedure.

The swab was then rotated twenty five times in a test tube containing 8 c c of broth, the end of the swab rubbing the sides of the tube. The broth, having been taken from an icebox kept below 40° C just prior to the inoculation, was immediately replaced in the icebox.

Owing to the number of cultures and the large amount of media required for each specimen, routine cultures could not be taken on a consecutive series of patients, so that patients were selected on the delivery floor more or less at random, breech presentations only being excluded because of the possibility of diluting the vaginal contents with meconium. In every instance a culture was taken from the vagina at the onset of the experiment to serve as a control. Following this the patient was instilled, and in general cultures were taken every four hours thereafter up to the end of the first stage of labor. Instillations were repeated at vary-

ing intervals from 4 to 8 or 12 hours, the maximum number of instillations in any one patient being 5 and the minimum 1, one instillation being employed more frequently than any other number.

In the technic for instillation of an antiseptic the patient was placed in the same position as for taking the culture. Prior to the instillation an alcoholic acetone solution of the same antiseptic as that to be used for instillation was poured over the labia, perineum and adjacent skin areas covering a wide surface and allowed to remain 3 to 5 minutes before the actual instillation. The antiseptic to be instilled was used in the same quantity in all instances, namely, 15 c c. This was drawn up in a blunt-bullet-shaped aseptic syringe described by Mayes, two sizes being used, the smaller, 2 cm in diameter for primiparae, and the larger, 3 cm in diameter, for multiparae. The labiae were again separated by the same technic as described above and the syringe gently inserted in the vagina until the vault was reached. The sterile gloved hand then approximated the labiae tightly about the syringe, while the antiseptic was gently instilled and the syringe gradually withdrawn. The patient's knees were then placed together and the bed-pan removed.

BACTERIOLOGICAL TECHNIC

As described in the foregoing, the culture media was continually kept in the icebox, removed only to be inoculated, and immediately replaced in the icebox. It was found that the cultures could be safely kept over night without appreciable increase or decrease in the number of viable organisms in the broth. The culture tubes were removed from the icebox when preparations were completed for inoculation into the various media. In most instances a 1:40 dilution of the original 8 c c of broth was made, and 0.25 c c of the undiluted and diluted broth was then placed in melted agar tubes to which rabbit blood had been added to make a concentration of 5 per cent. After thoroughly mixing the inoculum the media was poured into petri dishes, two plates being made of the undiluted inoculum, and two plates of the diluted inoculum. One of each of these plates was incubated aerobically, the other two being incubated under strict anaerobic conditions in the McIntosh-Fildes jar. For qualitative studies of the flora the tubes

of broth were incubated aëroically, and also Robertson's deep meat media inoculated for growth in liquid media under anaërobic conditions. All media were incubated for 72 hours at 37° C. Then the plates were removed and colony characteristics noted and counts made. Frequently, it was necessary to employ a low-power binocular microscope, because of the minuteness of the colonies, for identification and counting purposes. Stained smears were made from both the broth and the anaërobic deep meat media. Further identification was carried out only occasionally. In the above technic the

Chart I.—Colony counts of vaginal secretion, first stage of labor. Instillations of metaphen-in-oil 1:1000, No. 31051.

antiseptic action in vitro is reduced to a minimum by immediately diluting the small inoculum in a relatively large volume of broth. In the diluted broth, the deep meat media and blood plates, this error is further eliminated by the same principle.

The clinical material employed for comparative purposes is divided into four groups. In Group A metaphen-in-oil was used as the vaginal antiseptic, the alcohol acetone solution of the same drug being used to sterilize the skin of the external genitalia. Similarly in Groups B and C, mercurochrome and merthiolate, respectively, were used. In Group D, cultures were taken but no instillation nor external

skin preparation was carried out, and this group serves as a control.

GROUP A.—This group consists of 11 patients, 7 of whom were primiparae and 4 multiparae, instilled with a 1:1000 solution of metaphen-in-oil, metaphen being the anhydride of 4 nitro, 5 hydroxy-mercuri-orthocresol, $C_6H_2:CH_3, ONO_2, Hg$. The unusual antiseptic and disinfectant properties of this organic compound in vitro have been adequately demonstrated by Raiziss and Severac⁸ and many other investigators. Fifty-four cultures were taken, the minimum number being two and the maximum number ten in any individual case, while the minimum number of instillations the patient received was one and the maximum number three.

Chart I illustrates a more or less typical patient receiving metaphen-in-oil instillations, the upper curve being colony counts of plates cultured under anaërobic conditions, the lower curve being plates with the identical media and inoculum incubated under aërobic conditions. One notices that the aërobic count ends slightly lower than in the control count taken before the first instillation. In spite of the fact that the patient received three instillations, we see that in general the anaërobic count progressively increases. There is a tremendous difference in this particular patient between the colony counts under aërobic and anaërobic conditions, the anaërobic count usually being higher than the aërobic count, and frequently very much higher as is illustrated in this chart.

The general results following the instillation of metaphen-in-oil are to be seen in Table I, Group A. The total colony counts decreased in only 45 per cent of the patients, the remaining counts stayed the same or increased. The results are also just as inconclusive in the patients with premature rupture of the membranes. Plate cultures showing no growth were practically negligible, in fact, only once in the 54 cultures under aërobic conditions, and in no instance in the plates incubated under anaërobic conditions did we fail to obtain a growth. Likewise, none of the cultures in broth or deep meat media were negative. On the other hand, 73 and 90 per cent, respectively, of the patients cultured in this group showed constant organisms in each specimen of broth and deep meat media cultured. Streptococci were found consistently in each culture in the deep meat media from 8 or 73 per cent

TABLE I

of the patients cultured, and in each broth culture from 3 or 27 per cent of the patients cultured.

GROUP B.—In this group 5 per cent aqueous mercurochrome solution was used for instillation. There were 20 patients studied and a total of 52 cultures made. The group consists of 6 primiparae and 14 multiparae. The minimum number of cultures in any one patient being two and the maximum five. The minimum number of instillations was one and the maximum number two.

Chart II gives a graphic representation of the colony counts in two patients in

Chart II.—Colony counts of vaginal secretion, first stage of labor. Instillations of mercurochrome 5 per cent ag. sol., Nos. 40064 and 47131.

whom a single instillation of 5 per cent mercurochrome was given in each instance. In the first patient one notices that there are quite wide fluctuations with little or no apparent result from the instillation. In the second patient, on the other hand, there is quite a marked decrease in the first culture after instillation and a very marked decrease in the last culture.

In Table I, Group B, it can be seen that 95 per cent of the patients in this group showed a decrease in the colony counts under both aerobic and anaerobic conditions, the other 5 per cent remaining stationary. It is interesting to note that three of these patients had premature

rupture of the membranes and in each instance a decrease in colony counts was registered. In the blood agar plates, 19 and 11.5 per cent, respectively, showed no growth under aerobic and anaerobic conditions. Of the total broth cultures 17 per cent were negative and of all deep meat cultures 4 per cent had no growth. Forty per cent of the patients showed one or more constant findings in each broth culture, while 80 per cent had one or more constant findings in the deep meat media. Fifteen and 50 per cent, respectively, showed constant findings of streptococci in the broth and deep meat media. One

Chart III.—Colony counts of vaginal secretion, first stage of labor. Instillations of merthiolate 1:1000 ag. sol., No. 33469.

patient had a febrile puerperium, the temperature reaching 38° C. on two days.

GROUP C.—The instillation used was merthiolate, 1:1000 aqueous solution. There were 15 patients in all, 13 of whom were primiparae and 2 multiparae. Sixty-five cultures were taken, the minimum number being two and the maximum number eleven. The minimum number of instillations was one and the maximum five in any given patient.

Merthiolate is another organic compound of mercury, sodium ethyl mercurithiosalicylate. This antiseptic has come into prominent use and in vitro is a powerful bactericidal substance and is relatively non-

toxic when brought in contact with mammalian tissue.

Chart III illustrates the anaërobic and aerobic curves of the colony counts of a patient receiving three instillations and from whom eight cultures were taken. In this chart one sees again the wide difference between the number of organisms cultured under aerobic and anaërobic conditions and the gradual approximation of the curves and the marked diminution in the number of organisms in a given unit volume of vaginal secretion in the latter cultures.

The figures in Table I, Group C, show that 80 per cent of the patients had decreased counts under both aerobic and anaërobic conditions. In the five instances of patients who had premature rupture of the membranes in this group, all showed decreased colony counts in the aerobic plates and four decreased in the anaërobic plates while in the other patient the anaërobic plate counts remained approximately the same. Of the total plates cultured, 22 and 5 per cent showed no growth under aerobic and anaërobic conditions, respectively. Eleven per cent of all broth cultures in this group had no growth, while 3 per cent of all deep meat cultures were negative. Forty-seven per cent of the patients showed one or more constant organisms in each of the broth cultures, while 67 per cent of the patients showed constant bacteria in each of the deep meat cultures. Streptococci were constantly present in 27 per cent of the patients in all broth cultures, while 53 per cent of the patients showed streptococci to be a constant finding in the deep meat media. Four patients, or 27 per cent, had a febrile puerperium, one patient reaching 38° C. on two occasions, two patients with 38° C. on three occasions and one having rises to 38° C., or above, six times.

GROUP D.—No instillations were employed in this group, which consists of 15 patients, 8 being primiparae and 7 multiparae. There was a total of 44 cultures taken.

Chart IV illustrates two patients who received no instillations and who were more or less typical of this group. We see again the wide divergence between the lines, the upper line representing colony counts under anaërobic conditions, the lower line, colony counts under aerobic conditions. In this patient there was a

marked increase of the total colony counts. The second patient shows what are apparently normal fluctuations during labor, the final count on the anaërobic plate being slightly lower than the first count, and the final count under aerobic conditions being somewhat higher.

In Table I, Group D, we see that 53 and 47 per cent of these patients had decreased colony counts under aerobic and anaërobic conditions, respectively, the others remaining the same or increasing. There were three patients who had premature rupture of the membranes, and in one instance there were increased colony counts, one instance decreased colony

Chart IV.—Colony counts of vaginal secretion, first stage of labor. No instillations, Nos. 49133 and 37814.

counts and in the third patient the colony counts remained the same. Only 5 per cent of the blood agar plates were sterile under aerobic conditions and in no instance were the plates found to be sterile when cultured under anaërobic conditions. In only one instance, or 2 per cent, of the cultures did we fail to obtain a growth in broth and in no instance was the deep meat media sterile. On the other hand, 87 per cent of the patients in this group had one or more constant organisms in the broth, and 100 per cent of the patients had constant organisms in the deep meat media. Streptococci were present as a con-

stant finding in 33 per cent of the patients in all broth cultures, and in 73 per cent of the patients these organisms were constantly found in all the deep meat media. Four of the patients in this group had a febrile puerperium, the temperature rising to 38° C. or above on two occasions in two patients, three times in the third patient and four times in the last patient.

SUMMARY

Unfortunately, owing to the fact that we found a tremendous variation in the colony counts of different patients during the first stage of labor, it was impossible to correlate graphically the data of these counts.

Table I partially served the purpose but one cannot accurately express in it the extent of the decreasing or increasing, as the case may be, in the total counts. However, after carefully studying the figures we reached the same general conclusions that we reach from Table I.

It will be noted that the colony counts in Group A where metaphen-in-oil was instilled were practically duplicated in Group D where no instillation was employed. Again, in an analysis of the results obtained in liquid media we find that metaphen-in-oil exerted but slight bactericidal action in the vagina. Constant findings of one or more organisms in the deep meat media were noted in 100 per cent of the patients who received no instillations, while in the group of patients who received metaphen-in-oil as an instillation, 90 per cent had constant organisms in all the deep meat cultures.

In the same Table we see that the total colony counts decreased very markedly in Groups B and C, 95 per cent in the former and 80 per cent in the latter. These antiseptics were apparently also more efficient in the patients who had premature rupture of the membranes. Furthermore, constant findings in the liquid media show a considerable diminution from the control group or the group receiving metaphen-in-oil, while also in the liquid media and in the blood agar plates the percentage of sterile cultures was much higher than in Group A or Group D.

The relatively small number of patients in each group makes it impossible to draw accurate conclusions regarding the incidence of puerperal infection. However, when we note the number of patients who had constant organisms in the liquid media,

and particularly the number who had streptococci constantly present in each of the cultures one is led to the conclusion that puerperal infection is still a possibility in spite of vaginal chemotherapy with the agents employed in this study.

CONCLUSIONS

1. Mercurochrome, 5 per cent aqueous solution, and merthiolate, 1:1000 aqueous solution, are both fairly efficient vaginal antiseptics during the first stage of labor. They decreased the colony counts with marked regularity and in a few instances there was at least complete temporary sterilization of the vagina.

2. Metaphen-in-oil in the concentration employed is not an efficient vaginal antiseptic during the first stage of labor, the result being approximately the same as in the group of patients who received no instillation.

3. In general the colony counts on poured plates were very much higher when incubated anaerobically than they were when incubated aerobically.

4. In a considerable number of patients each had constant organisms in her series of inoculums in spite of instillations of the more efficient vaginal antiseptics.

5. The necessity for carefully controlled experimental data, cultures being incubated under both aerobic and anaerobic conditions is necessary to accurately determine the value of an antiseptic instilled in the vagina during the first stage of labor.

We wish to express our gratitude to Dr. Cloyce R. Tew of the New York Hospital Staff for making the Charts and Table.

THE PATHOLOGY OF SENILE CATARACT

DANILL B KIRBY MD FACS

From The Eye Institute of The Presbyterian Hospital in the City of New York and the Department of Ophthalmology of The College of Physicians and Surgeons Columbia University New York City

The study of the pathology of senile cataract is interesting because it brings out many significant and practical points for those who are doing cataract surgery. The subject embraces not only the features seen in fixed and stained microscopic specimens of the lens but also the knowledge gained from embryological, anatomical, chemical and slit-lamp microscopical studies. The present methods of fixation and hardening produce many artifacts and do not permit demonstration of the delicate pathological changes observed in the living eye. No attempt will be made to cover the entire subject in this paper.

Cataract may be defined as any opacity of the crystalline lens. Senile cataract refers to the opacities developing in the elderly or in those who have reached or passed the adult stage.

THE UNIQUE PHYSIOLOGY OF THE CRYSTALLINE LENS—The crystalline lens as an organ is unique in that it is composed entirely of epithelial cells, is suspended between the aqueous and the vitreous, and has no circulation of its own. Its nutrient and growth materials and its waste products are conveyed to and from the lens by the aqueous humor which is formed by the ciliary body. The exchange with the lens is by a process of osmosis and selective absorption and excretion.

A systematic study of the various parts of the lens and their relations will bring out many points of interest. We will consider I The Zonule or Suspensory Ligament of the Crystalline Lens, II The Vitreous and the Lens, III The Capsule, IV The Epithelium, V The Nucleus, and VI The Cortex.

I THE ZONULE OR SUSPENSORY LIGAMENT OF THE CRYSTALLINE LENS

The zonular fibers are developed by protoplasmic processes which are formed at the union of the cells of the optic vesicle

The author is indebted to Dr John M. Wheeler for the opportunity to study cataract for the past ten years and to Dr A. B. Reese for the loan of his specimens for examination.

and surface ectoderm in the contact which stimulates the origin of the lens. These processes are later drawn out into zonular fibers which stretch between the retina at the ora serrata, the ciliary body, and the equator of the lens. The attachment of the fibers to the retina may account for the development in certain cases of disinsertion of the retina at the ora serrata after sudden trauma to the eye head or body. The indirect force is exerted on the crystalline lens which is suspended almost as a free body. The jar may cause the disinsertion through the pull on the zonular fibers. More often, especially in the case of direct eye trauma, the zonular fibers break at the equator of the lens and partial or complete dislocation of the lens results. It is possible that traction on the zonular fibers during intracapsular extraction may be responsible for the cyclitis which develops in some cases as also for disinsertion and detachment of the retina.

The condition and age of the zonular fibers determine their elasticity, resiliency, resistance, or fragility. In eyes with dislocated lenses, either congenital or traumatic, they may appear very thin and attenuated. In nearly all cases of intracapsular extraction the zonule ruptures at the equator of the lens so that very little of the zonular fibers adhere to the lens. In certain instances, one may find broken fragments or isolated whole zonular fibers lying on the hyaloid, looking very much like thin strands of silkworm gut.

It is difficult to judge the condition of the zonular fibers before operation. Knapp has expressed the opinion that the zonule of almost any person over 65 years should break without undue force. He has also made the observation that the zonular fibers are very fragile in cases of glaucoma. They are also very fragile in certain cases of hypermature cataract.

II THE VITREOUS AND THE LENS

The vitreous is formed by ectodermal and mesodermal elements and never develops any actual adhesions to the lens.

The hyaloid membrane is a real entity and is in contact directly with the posterior capsule of the lens. The so-called ligamentum hyaloideum capsulare is merely a close apposition of the hyaloid and the posterior lens capsule.

THE RETROLENTAL SPACE.—There is no aqueous humor as such in the retrolental space except in a possible capillary zone between the hyaloid and the posterior lens capsule. The dark space which is observed directly behind the lens is the anterior or primary vitreous which has less fibrillar structure than the rest of the vitreous.

FLUID VITREOUS.—The anterior vitreous more frequently than the whole vitreous becomes fluid and loses its viscosity and gel formation. One must assume that the pressure one exerts in the expression of cataract is counterbalanced by the vitreous. For the proper reaction to this, the anterior vitreous must be in good condition. The recognition of fluid vitreous may be significant if it determines the type of operation and the procedure.

DISLOCATION OF LENS.—The ligamentum hyaloideum capsulare is probably not important in holding the lens in place, but the integrity of the hyaloid may determine the final position of the lens when it is dislocated. If all the zonular fibers are broken and the lens is free, it will remain anterior of the hyaloid is not ruptured. If it is ruptured, then the lens will probably drop back into the vitreous unless it is held forward by the iris or by adhesions. In cases of dislocation, therefore, it is well to look for the condition of the hyaloid and whether or not the vitreous comes forward into the anterior chamber. In cases of hypermature cataract, the zonular fibers are apt to be very fragile, so that dislocation may occur very easily.

III. THE CAPSULE

The capsule is formed by the lens epithelial cells first as a secretion or cuticula which surrounds the lens vesicle. Later it appears as a glass membrane formed by accretion from the interior. The material is secreted by the epithelium and forced between the epithelial cells and the previously existing capsule. This mode of formation explains the gradually increasing thickness of the capsule with age and the thinness of the posterior lens capsule as compared with the anterior. The capsule always appears and remains trans-

parent except for the condition of exfoliation of the most superficial lamella.

EXFOLIATION OF THE ZONULAR LAMELLA OF THE ANTERIOR LENS CAPSULE.—The glass membrane of the capsule appears fused into a single layer except for the most superficial lamella. This may fragment, strip off, and exfoliate. There is usually a characteristic frosty appearance due to the minute grayish opacities which develop and are rubbed off by the action of the iris. There may remain a disk of opacity with a curled or frosty border in the position of maximum contraction of the pupil. It may or may not be associated with glaucoma due to blocking of the angle by the small particles. This condition of exfoliation of the most superficial lamella of the anterior lens capsule is a degenerative change and may indicate fragility of the zonular fibers which are inserted into this layer which is sometimes known as the zonular lamella.

THE REACTION OF THE CAPSULE TO TRAUMA AND OPERATION.—It is difficult before operation to judge the thickness, tension, and resistance of the capsule. It may be distended and smooth or relaxed and wrinkled. This may indicate the slack that will be taken up by the forceps or other instrument used on the capsule. In its reaction to traction and to incision the capsule behaves as if it were slightly elastic, very much like cellophane. In general it may be said that the relaxed capsule will respond better to the application of traction by the forceps or vacuum cup than the normally tense or distended and stretched capsule. Rupture occurs in the anterior or equatorial region. The capsule may be incised precisely with a sharp cystotome, the knife beak of which should be (1) very small so as not to cut into the cortex and not dig into the nucleus, (2) bevelled with the cutting stroke so as to cut keenly and not tear the capsule; it tears if a dull cystotome is used. The type of capsule forceps best suited to preserve the integrity of the anterior capsule in intracapsular extraction is one which has smooth edges and sides. A relaxed capsule will stand considerable traction before rupturing. A tense capsule will stand hardly any. Once a capsule starts to tear, it may rip up and tear off at the equatorial region where it then tears off the zonular fibers. In principle, as far as the capsule alone is concerned, the vacuum cup is best

suted for application to the capsule, as it gathers it in from all points equally and exerts a smoother and more even traction with less danger of rupture. The teeth of the toothed forceps such as are used to remove a portion of the anterior capsule should be short so that the bite will be shallow and will not disturb the deeper portions of the cortex.

Wounds in the capsule produce defects in the glass membrane which are never replaced by capsule tissue. They may be plugged by cortex or by lens epithelial cells or their products. The capsule acts as if it were elastic. It retains its true character even in the presence of severe inflammation of lytic character.

IV THE EPITHELIUM

The lens epithelium as such represents the only living cells in the lens. There are two functions of the epithelial cells: (1) to form new fibers, and (2) to form a secretion which controls the life and transparency of the fibers already formed. It is an interesting conception that the lens epithelial cells are quite active and divide regularly either by mitosis or by amitosis and then move off radially to the equatorial region to take part in the formation of the cortex. The new fibers formed here are pushed centrally and lose their nuclei. They exist probably under the influence of the secretion of the living epithelial cells and thus maintain their transparency and optical properties. The epithelium continues to form new fibers continually throughout the life of the individual unless cataract supervenes. In the development of cataract the epithelium usually dies or degenerates. It may proliferate and in some instances where the outermost epithelial cells have become detached from the cortex, may grow to line the posterior capsule. In cases where cataract follows inflammation, flat opaque cell forms may develop beneath the capsule to add to the general opacity. In after cataract, flat epithelial cells may be formed or crystalline spherules of hyaline material, so-called Elschnig's spheres, similar to the glass membrane capsule may be secreted.

V THE NUCLEUS

The nucleus of the lens consists of the hardened dehydrated and compressed fibers, which have formed first in the outermost layers of the cortex and have gradually been pushed toward the center of the lens.

NUCLEAR CATARACT — Physiological sclerosis of the lens begins with the earliest hardening of the fibers in the embryo. The cells of the posterior wall of the lens vesicle grow forward, lose their nuclei, and are finally compressed to the center of the lens. The fibers formed from the fetal period to that of adult life are likewise compressed. The process entails dehydration and sclerosis or hardening and the formation of the so called nucleus which may be divided according to the zones of separation into the embryonic, the infantile nucleus, the adolescent nucleus, the adult and the senile nucleus. In certain cases of extreme sclerosis there is no soft cortex, the outer layers becoming hard and forming a nuclear cataract which involves the entire lens.

Loss of accommodation accompanies physiological sclerosis and at a certain age there develops presbyopia through the formation of an unyielding nucleus. Clinically, all accommodation has gone about the age of seventy years and hence one may say that the entire lens has become hard and unyielding and that there is no longer any pliable cortex.

Through a process of pathological sclerosis there develops nuclear cataract. The hardening of the lens proceeds more quickly and with less uniformity than in the normal. The hardened material in such instances is no longer hygroscopic. There may develop abnormal and irregular interfaces, pressure surfaces, differences in refraction of the component parts of the lens, abnormal chemical combinations of the lens protein, all of which result in nuclear cataract. Colorations from amber hue to mahogany or cherry red, brown or black cataract develop. Lenticular myopia or "second sight" usually intervenes and may reach a high degree in certain cases. In some, lenses of double foci may form. The interference with vision is not so much through actual opacity as through the haze of the interfering lens media. It is difficult to get good pathological sections of such hard material. The recognition of the degree of hardening of such a cataract by slit-lamp microscopy is important as it is well known that in the great degrees where there is no longer any hygroscopic cortex remaining, the capsulotomy operation is admirably suited, the entire contents of the capsule coming away. There is no need for intracapsular extraction in these cases.

VI. THE CORTIX

SENILE CORTICAL CATARACT.—The senile cortex represents the outermost lens fibers. These fibers may be still soft and pliable. The protein in the fibers is still hygroscopic and capable of considerable swelling. The incipient form of senile cortical opacity is characterized by the development of subcapsular vacuoles or globules, separation of the lamellae, splitting of the sutures, and cortical haze. All of these features may be explained by the conception that a colloidal fluid which has been attracted through the capsule or has been extruded from its combination with the lens protein in the fibers is forced under pressure through the normal interfibrillar diffusion spaces. (*Note:* None of the features referred to can be accurately demonstrated in the micropathological specimen as all are altered in the process of fixation and hardening. It is interesting that due to the anatomical structure of the lens, symmetrical anterior and posterior planes of the lens are involved by the processes of water-splitting of the sutures and separation of the lamellae.

After cataract is initiated, it may be that enzymes help to carry on the work of destruction of the lens protein. Each living cell may carry or be exposed to its own specific destructive agent which will reduce it to its original elements. In the case of the lens cells, the enzyme may coexist with the cell or be brought to it by the aqueous which enters under pathological conditions. In the case of traumatic cataract, the aqueous humor, which under normal conditions carries nutrient and growth materials to the lens and transports its metabolic products, proves destructive to the lens fibers and protein. The hygroscopic lens material swells and its destruction is most probably effected by the lytic action of the enzymes brought in by the aqueous or ever present in the cells waiting for the time to act and destroy the protein. We know that the water-soluble protein of the lens fibers is constantly being removed. This is probably the physiological action of these proteolytic enzymes. In conditions which initiate senile cortical cataract, these enzymes may become abnormally active.

IMMATURE CATARACT.—From the incipient stage, progress in opacity and haze is made by extension of the processes referred to and also by denaturation and coagulation of the lens protein which has

come by lysis from the lens fibers. There may form a smooth homogeneous coagulum or clot or by partial aggregations of the denatured material there may develop different morgagnian globules. These are seen best in their discrete forms in the fissures. They may be of (1) granular nature with dull reflex and with no surface membrane, simply an aggregation of granules into minute spheres which are suspended in the liquor Morgagni, (2) globules with a surface membrane of high luster and reflex and with pearly or opalescent fluid content, or (3) a form in which the surface membrane is present but the contents are dull and a solid greyish hue.

Complete destruction of the lens fibers is finally accomplished. Pathological specimens show the swollen, broken fibers mixed with fluid and debris, pultaceous, granular and other material. The swelling of the lens cortex and distention of the capsule in the intumescent stage is accomplished by the intake of a great excess of water, because of the hygroscopic nature of the lens protein. The spontaneous rupture of the capsule under these conditions has not been reported, but it seems possible. In cases of deficient anterior chamber drainage with a tendency to glaucoma, the intra-ocular tension may be elevated by the further obstruction incident to the pressure on the iris root.

MATURE CATARACT.—The transition from the intumescent stage to the mature stage is accomplished by the abstraction of excess water from the lens. This is effected only after complete destruction of the hygroscopic lens protein. The lens protein byproducts no longer have the affinity for excess water. Abnormal organic and inorganic compounds now are attracted and enter under the conditions of altered permeability of the capsule. The most important of these abnormal substances are the fats and the calcium compounds. In the early stages the fats form the surface membranes for the morgagnian globules, the linings for the split sutures, and the coatings for the lamellae. In the later stages, they mix with the protein debris to form the pultaceous masses.

HYPERMATURE CATARACT.—The final stages of senile cortical cataract are brought about by the removal of the excess water and soluble lens protein material through the capsule. There remain in the capsule the degenerated epithelial cells, the pultaceous mass of insoluble cortex protein

mixed with abnormal organic and inorganic materials, and the hard, resistant nucleus. The hypermature forms are

(1) The morgagnian cataract, a condition produced by further disintegration and digestion of the cortical material. There is a turbid suspension of granular debris and hard nucleus in cloudy amber fluid in the flaccid sac formed by the capsule. The sections of morgagnian cataract show the hard nucleus placed eccentrically in the most dependent portion of the capsule sac. It is conceivable that the enzyme action which produced the digestion and liquefaction of the cortex might go on to cause complete disintegration of the contents of the capsule. The zonular fibers in these cases are apt to be quite fragile so that intracapsular extraction may be in order.

(2) The chalky cataract, reached by greater calcium deposit with hardening of the greater part of the lens. These forms can easily be recognized clinically. The chalky form is enclosed in a wrinkled capsular bag. It is composed of dense amorphous granular material with irregular spotty calcareous deposits outermost and surrounding the remnant of the hard nucleus. From the appearance of the pathological specimens it would be difficult to separate the wrinkled capsule from its irregular contents. The zonule in these cases is fragile so that intracapsular extraction may be indicated. The wrinkled and relatively tough capsule in both the morgagnian and chalky forms affords easy purchase for the traction instrument.

POSTERIOR CORTICAL CATARACT—This type begins with vacuoles or globules in the posterior cortical layers. Between and around these features develop irregular deposits of opaque material. The posterior cortical area of the lens is the most poorly nourished. The vitreous is here in contact with the posterior capsule and the ends of the youngest fibers reach the posterior capsule in this area. Toxic substances in the vitreous or faulty nutrition of the lens will affect the posterior cortical area first. It is difficult to demonstrate this type microscopically.

ANTERIOR AND POSTERIOR SUBCAPSULAR CATARACT—This is a rapidly progressive form found in so called early senile forms as well as in complicated or toxic conditions, either local or systemic. It is seen in tetany, diabetes in the young neurodermatitis, detachment of the retina. It is

not always a sign of these complicated conditions. Many of these cataracts have been removed in early senile forms and excellent visual results obtained. The opacity begins with anterior and posterior subcapsular vacuoles. These increase in number and size and there develops a cloudy swelling of the cortex which quickly disintegrates. An intumescent cataract results. The complete opacity or mature form may be reached very quickly, even within a few weeks. The cataract is best removed by the capsulotomy method.

Under pathology of the lens must also be considered that very interesting allergic reaction which occurs in certain sensitized individuals. It is possible for a person to become allergic or anaphylactic to the protein of his own lens. Verhoeff and Lemoine have demonstrated that such a state does at times exist in otherwise normal persons. They state that if the lens capsule in such an individual is ruptured by injury or operation and dead or dying lens fibers remain in the eye, a more than usually violent local reaction is experienced. These authors describe the usual features of subacute endophthalmitis in these cases in addition to the numbers of large mononuclear phagocytes attacking the disorganized lens. Verhoeff now thinks that the method of desensitizing such individuals to their own lens protein is unsatisfactory and that the cataracts in these patients had best be removed by the intracapsular method.

CLASSIFICATION OF LENS OPACITIES—Lens opacities should be classified according to their light obstructing properties. The transparency of any medium is judged by its property of light transmission, that is the ratio of incident light to transmitted light. The term opacity used in speaking of changes in the lens which partially obstructs the transmission of light is only relative, for no matter how dense or complete a cataract is, it remains translucent and under proper conditions, scleral transillumination in the presence of uncomplicated cataract will produce a light reflex through the pupil. Every case of complete cataract should be transilluminated. The degree of partial lens opacity may be expressed subjectively in terms of its ability to obstruct the vision or objectively in its interference with the fundus reflex. For the latter, the terms used in denoting atmospheric conditions are good. (1) Haze, expressing the stage of vacuoles, water-

split sutures, and lamellar separation or early nuclear cataract; (2) nebula, the stage of smooth coagulum of the colloid fluid or of the fewer numbers of morgagnian globules; (3) grey cloud, the early stage of infiltration with fatty and other organic and inorganic material; and (4) black cloud, the stage of completion of the aggregation of the coagulated particles, of lens protein with further infiltration by abnormal material. The latter are represented by such dense features as the equatorial wedge opacity of Voft which forms after lamellar separation, the familiar "rider" or "spoke" which is seen in symmetrical anterior and posterior fissures or split sutures, the immature, mature, and hypermature forms of senile cataract.

The combination of several of the partial opacity features in the same or different stages make a picture of immature cataract which is very difficult to evaluate in objective terms for purposes of record. Photographs do not give a true picture as they are taken by incident light. Drawings of the features seen with the aid of incident light, do not tell the whole story as they are on different levels. Fundus reflex drawings are probably the best for the record of the individual case. They may be drawn both normal size with the aid of the aperture of the reflecting ophthalmoscope and in magnification with the + 16.00 D or + 20.00 D lens at its proper focus. For comparison at succeeding examinations there is need for controlling the light and of duplicating the other conditions of the examination.

In summary and conclusion it is only necessary to say that senile cataract has been studied from its very embryological, its chemical and its anatomicopathological background. Most important clinically is the study with the ophthalmoscope to determine the degree of transparency remaining or conversely the degree of opacity and the study with the slit-lamp microscope to learn of the type and stage of cataract present. The information gained may influence our judgment materially in the decision as to the technic to be employed in the individual case.

780 PARK AVENUE

DISCUSSION

DR. D. F. GILLETTE, *Syracuse*: When you have been able to study Doctor D. B. Kirby's paper you will the more appreciate its scientific and clinical values.

We have been shown that the zonule developments after the third month when the rim of the optic vesicle grows forward to the ciliary region, at which time fine fibers grow back into the newly formed vitreous. Later, from the region of the ciliary body heavier fibers grow forward at right angles through the marginal group, forming a complex structure of fibers, extending from the ciliary body as far back as the ora serrata to the lens capsule.

Examination of a fresh specimen shows the zonule as a thick band—its anterior surface extending from the lens equator to the anterior ciliary processes, while its posterior surface, which is more curved, passes from the lens capsule along the inner surface of the ciliary body to the ora serrata.

These surfaces appear made up of delicate strands separated by a gel similar to the vitreous. The anterior and posterior surfaces are separated by an irregular meshwork of fibers, whose interspaces are filled with fluid and gel.

The coarser fibers contained in the posterior group extend from the recesses of the ciliary processes to an irregular zone about 2 mm. broad concentric with the equator, slightly broader anteriorly.

The examination of an intracapsular lens recently delivered shows the fibers to be torn at or near the capsule. These fiber stumps which can be teased into fine threads have a brush-like footing on the capsule, which appears elevated at the site of attachment.

This same condition must obtain in the accommodation relaxed lens—evidence that some traction occurs at these points.

This suggests the possibility of a separation of the capsule from the lens matter at these points varying with ciliary action and the change in elasticity of the lens cortex. This would result in a biological change, altered refractivity of the lenticular cells and interspaces, and eventually opacities. Other possible etiological factors are injury to the zonule, disease of the ciliary process and changed intra-ocular fluid.

The position of the suspensory ligament makes it almost impossible of direct examination save after iridectomy or dislocation of the lens—when in direct or reflected light it appears much like the vitreous in structure.

The fragility of the zonule is not indicated by the condition of the capsule and lens substance, so choice of operation must depend on experience.

Professor A. Elschmig has described a helpful procedure to determine the choice of operation, *i. e.*, the most satisfactory cases for intracapsular extraction are those in which the pupil readily dilates with the introduction of not more than two drops of one per cent homatropine.

Those not dilating are best suited for extracapsular operation.

A still further help in cataract surgery was given by Dr. W. Atkinson, *i. e.*, a method of local anesthesia (akinesia and orbital injection within the cone), that materially helps in the intracapsular delivery. When satisfactorily obtained, this type of anesthesia allows the lifting of the lens without undue counter pressure.

THE PRESENT STATUS OF THE FEMALE SEX HORMONE FROM THE CLINICAL STANDPOINT

ROBERT T FRANK MD

From the Gynecological Service and Laboratories of Mount Sinai Hospital New York

Purely clinical investigations of the many functional conditions due to disturbances of the female sex cycle permit of numerous interpretations as to causation, very few of which it is possible to confirm by proof. With the methods devised by our group,¹ it has been possible to analyze the underlying hormonal disturbances. Our studies have the same application that basal metabolic tests, for example, have in the investigation of functional thyroid disturbances, or chemical studies of calcium and phosphorus in parathyroid trouble.

Our numerous previous publications² make it unnecessary to give any detailed description of the methods and technic. Suffice it to say that the female sex hormone or estrogenic substances in both the blood and urine can be determined. Similarly the anterior pituitary gonad stimulating hormones can be titrated in the blood and also in the urine. For the estrogenic substance, the vaginal spread of the castrated rat is used as indicator. For the prepituitary or prepituitary-like gonad stimulating substance, the effect produced on the ovary of the immature rat is used as a test.

By means of these methods we have now studied a large number of normal and diseased women. The object of this paper is to show some of the more striking deviations and how these determinations help in diagnosis and eventually may bear fruit in our therapeutic endeavors.

GRAPHIC NOTATION OF RESULTS

Blood investigations are shown above the base line and represent weekly specimens of 40 c.c. of vein blood. The situation of the black dot represents the amount of female sex hormone found in 40 c.c.—0 to 2 equals 0, 2 to 4 means an increasingly positive reaction, 4 being the full reaction or 1 full M U to 40 c.c. (Fig 1).

The small circle represents the gonad stimulating prepituitary substance obtained from the same 40 c.c. of vein blood, 2 equaling a slight ovarian reaction, 4 a complete ovarian reaction (Fig 1).

Urine—Beneath the base line. This represents the total excretion of female sex hormone in the urine, each block representing 3 days. The numbers to the left indicate the total excretion in M U for 3-day periods. The average excretion

of a normal fertile cyclical female is between 1200 and 1500 M U monthly with two well marked periods of increased excretion the one falling about the 14th day, the other centered about the 21st day of the cycle (Fig 1) M U = Mouse Unit.

UNDERFUNCTION—Our studies have shown that a large group of women, which includes most of those with oligomenorrhea, amenorrhea, sterility, and dysmenorrhea, have sluggish and underfunctioning ovaries. In most instances this ovarian underfunction must be ascribed to some disturbance of the pituitary, but in the majority of cases this pituitary disturbance cannot be demonstrated.

Amenorrheas of all varieties (obesity, asthenia, so called "essential" as well as those secondary to other endocrine troubles—pituitary tumor, Simmond's disease, Addison's disease, etc., can be divided into three varieties although clinically they appear absolutely identical. This classification is based on the amount of female sex hormone either found in the blood or excreted in the urine and the prognosis will be found proportional to the amount found, as shown in Fig 2.

The same classification applies to sterilities, after all mechanical and organic disturbances have been excluded, the likelihood of impregnation depending upon the hormonal picture.

Most of the dysmenorrheas likewise fall into the underfunctioning class, but prognostically the hormonal titer is of no help.

There is another type of amenorrhea again clinically indistinguishable from others in which continuous overfunction of the ovaries produces amenorrhea (polyhormonal amenorrhea). This variety is unusual, perhaps most often combined with polycystic ovaries, and needless to say requiring entirely different treatment than the underfunctioning type.

OVERFUNCTION—Overfunction of the ovaries most often documents itself by excessive, prolonged, or irregular bleeding. This classification does not apply to organic diseases due to fibroids (Fig 5) or

show the same symptoms—flushes, sweats, arthritic pains, physical and mental depression—the hormonal picture varies greatly after the ovaries have been removed and irrespective of whether the uterus is retained or not

In from 20 to 30 per cent of cases the prepituitary hormone in the blood is greatly increased. In the others it is normal or diminished in amount

Fig. 4 Organic uterine bleeding—inflammatory. Very poor ovarian function

mole and chorionepithelioma (particularly in the occurrence of metastases in both male and female), but also in determining the death of the fetus when combined with our blood test,⁴ in the diagnosis for adrenal tumor, and in some instances of pituitary diseases

As these tests are both time consuming and expensive, we have limited ourselves to cases which present special interest and

Fig. 5 Organic uterine bleeding—submucous fibroids. Very poor ovarian function

Fig. 6 Graphs of 5 menopause cases. All have severe neurovascular symptoms showing great variation of hormonal condition both of prepituitary and female sex hormone

After the onset of the normal menopause, as evidenced by the cessation of bleeding, the ovarian function may continue for months or years, in a diminished fashion, just as in the amenorrheas, or may be abruptly abolished (Fig 6)

This is of importance as it readily shows why the same therapy, if there be such, may work in certain instances and fail in others

These hormonal investigations are likewise of use not only in the commonly employed pregnancy tests of Aschheim and Zondek, and Friedman,⁵ to determine the presence of pregnancy, and also quantitatively to help in the diagnosis of hydatid

have likewise tried to apply the knowledge thus gained, to therapy

In underfunction of the ovaries, we have realized that none of the measures at our disposal, except purely hygienic ones such as reduction of weight in obesity or increase in weight and improvement in general condition in asthenia were of any use. We have so frequently seen improvement or cure of amenorrheas and sterility, observed over a long period of time, without any therapy, that we are fully convinced that the therapeutic results found so widespread in the literature are accidental or coincidental

In the treatment of overfunction of the

ovaries our therapy, on the other hand, has been extremely successful, but it has been based entirely on the well-recognized gynecological methods such as curettage, x-ray to the ovaries, in extreme cases, hysterectomy, and in the younger group of puberty bleedings, injection of minute quantities of moccasin venom (method of Peck)⁶.

WHOOPIING COUGH CURED BY MUMPS

Two cases of whooping cough seemingly cured by mumps in a few days are reported by Dr. Edmund W. Klinefelter, of York, Pa., in the *A. M. A. Journal*. Three children in the same family, it seems, developed particularly severe and distressing cases of whooping cough in the last week of February. "Paroxysms were occurring from three to four times every hour." Treatment relieved the two younger children, aged 14 months and 3 years, respectively, but nothing seemed to help the oldest, a boy of 5. On March 6, the boy developed a large swelling on the right side of the face which proved to be mumps. From that day on there were no more paroxysms. Nourishment was taken without coughing or vomiting. At times there was a slight cough but no typical whooping cough. By March 12 the child was perfectly well with a normal temperature and no evidences of whooping cough or mumps. From March 6, no medication was administered.

March 9 the 3-year-old child developed a swelling on the right side of her face. Examination showed that this child also had a typical case of mumps. The temperature by rectum was 101° F. Inspection of the throat at this time did not elicit a paroxysm. With the onset of the mumps there was likewise in this case an abrupt

cessation of the coughing paroxysms. By March 10 the temperature was normal and medication was stopped. By March 17 the mumps had completely disappeared and the child was perfectly well. Neither during nor after the attack of child suffered from typical whooping cough paroxysms.

Up until the middle of May, the 14-month-old child suffered from typical whooping cough paroxysms. From May 15 on there was gradual improvement. The intermittent administration of antipyrine, balladone, and amylal served nicely to control the cough in this child.

The doctor goes on to say that numerous cases are reported in medical literature showing that at times one disease may exert a favorable or curative influence on another disease. It has been reported that whooping cough can be checked during the eruptive stage of chickenpox. However, after the disappearance of the eruption the paroxysms again become severe. Apparently vaccinia at times exerts a favorable influence on whooping cough. Tuscherer observed two cases of whooping cough that were suddenly checked by an attack of measles. A review of the literature has shown no report of a case of whooping cough benefited or cured by an attack of mumps.

PENS NEED SHARPER POINTS

Experts assert that there are hardly a hundred competent medical writers in our country to-day, and some authorities insist that there are hardly more than ten or twelve, according to the *A. M. A. Journal*. Yet it is a fact that in the field of medical science, many men have gained note by their ability to express themselves in

good English succinctly, rhythmically and accurately. The opportunity is available to every one who cares to take the trouble and the time to perform competently in the field of medical letters. In the field of preparation for sound literary expression, particularly, we are told, preliminary education to medical training seems to be failing miserably.

THE LEUKOCYTES IN SKIN DISEASES

R H RULISON, M D

New York City

A review of the literature leaves a rather confused idea as to which dermatoses involve changes in the white blood count. Books on hematology give findings in skin conditions which do not agree with those collected by dermatologists, and dermatologists disagree among themselves.

The author had hoped to present the results of a fairly complete compilation on this subject, which in a few diseases, included a large series of cases, but study of the figures convinced him that such a compilation was valueless.

The writer did not willingly discard his tabulations, for they represented considerable work, but conference with a statistician showed that the absence of uniform technique, the omission of data needed to properly weight the figures, and the difference in approach to the problem by different investigators, laboratory and clinical, were sufficient sources of error to make the figures meaningless.

It would be well here to contrast the older methods of classifying the white blood cells with that commonly used today, because these changes explain the difficulty encountered in trying to combine the findings reported by different investigators.

Considering only the cells present in health, the white blood cells are divided into two main groups: (1) those with hyaline, and (2) those with granular cytoplasm. In the old classifications the hyaline cells comprised the large and small lymphocytes, the large mononuclears, and the transitionals, while the granular cells included the polymorphonuclears, the eosinophiles, and the mast cells or basophiles. The modern method of grouping combines the small and large lymphocytes in one column and the large mononuclears and transitionals, now called the monocytes, in another. The polymorphonuclear cells, instead of being tabulated in one column, as was the old custom, are now split into four or five groups, arranged with reference to their maturity. At present the Schilling¹ hemogram has come to be generally used. Here the differential

count is recorded in columns from left to right, beginning with the basophiles, the eosinophiles, and the four types of neutrophils (the more immature forms being recorded first), then come the lymphocytes, and last the monocytes. With repeated counts tabulated in this uniform manner it is possible to determine what are called left or right "shifts" as a disease progresses, and these findings often have prognostic value. This newer classification has many advantages, but most of the literature dealing with the white blood cells in dermatoses is based on the older methods.

The technique of the differential count is not adequately standardized. It begins to vary *ab initio*. Factors which have a bearing on the results are the method of cleansing the skin, the site chosen for puncture, the number of drops discarded before choosing the one to be used for the smear, the use or avoidance of pressure in obtaining the drop, the method of spreading and drying the smear, and the portion of the smear selected for counting. In the matter of staining confusion exists. There are three principal methods: (1) the haematoxylin and eosin, (2) Ehrlich's triacid, and (3) the Romanowsky stains. The latter has several modifications (Wright, Leishman, Giemsa). A slight change in the acidity changes the staining properties so that errors in classification of cells may develop. Furthermore, supravital staining and examination of leukocytes, unstained, under the dark-field microscope seem to give results which are not in accord with those reported after examination of the dead cell.

Aside from these technical details, there are physiological variations in the blood picture, depending on such factors as the age, altitude, the hour selected for the puncture, the relation to food and exercise, menstruation, pregnancy, and possibly some others. A number of pathological conditions, some of them difficult to detect, may also affect the count.

However, this investigation has led the author to two conclusions which he wishes

to state emphatically: (1) that the differential leukocyte count is only approximate, and (2) that a single count may be misleading. If dependence is to be placed on the leukocytic picture, repeated counts must be made.

In the order which seems to be most generally accepted, the author will note the conditions in which there is more or less general agreement as to the utility of differential white blood counts.

There is first leukemia cutis. It is a proven fact that in this disease a differential count makes the diagnosis possible. However, it must be remembered that a microscopic study of the skin itself is necessary to separate the true from the nonleukemic eruption. At dermatological meetings it is not at all uncommon to have the question of an aleukemic form of leukemia brought into the diagnostic discussion. The author thinks that for practical purposes this variation can be omitted. He has never seen this condition with leukemia cutis and thinks its occurrence must be rare. There is, in addition to lymphatic leukemia, a myelogenous leukemia and possibly a rare type for which the name eosinophilic leukemia has been suggested. In none of these forms are skin manifestations common.

The second dermatosis in which valuable information may be obtained from a differential count is scarlet fever. Reference to several standard works will verify the following statements: There is always a leukocytosis with a marked neutrophilia accompanied by an eosinophilia. The finding is unique and a real diagnostic aid, for eosinophilia in an acute infection does not ordinarily appear until the stage of convalescence is in sight. In scarlet fever it is usually present early. Reduction in the eosinophile cells during the acute stage of scarlet fever is cause for a grave prognosis. However, the attending physicians at Willard Parker Hospital say that these statements are much too emphatic, that qualifying adjectives must be inserted, and that no dependence is placed on the white blood count in scarlet fever, for either diagnosis or prognosis, in the hospital which cares for New York City's contagious-disease patients.

Erysipelas is another condition exhibiting changes in the white blood cell count. There seems to be some difference of opinion, but the majority find a leukocytosis with neutrophilia and a marked shift to

the left, that is, a relative increase of the younger forms of neutrophiles as compared with the older forms. This is the expected picture in infections of an acute type, and is also found in severe pyodermas.

In chronic urticaria eosinophilia is usually present, and Hazen, in a recent unpublished paper read before the Southern Medical Association, points out that this eosinophilia is accompanied by a basophilia, which is also found in bronchial asthma. This adds further evidence to the general impression that the two conditions are closely allied and are both allergic. Hazen did not find the basophile increase in erythema multiforme, although urticaria and erythema multiforme are often thought of as closely allied conditions; nor does it occur with any constancy in eczemas due to an allergic state.

A number of writers have stated that the bullous dermatoses, especially dermatitis herpetiformis, are characterized by eosinophilia. While eosinophilia is usually present in these conditions, it is not constant and therefore cannot be depended on for diagnostic purposes. However, an exacerbation of the eruption is often preceded by an increase in the eosinophile count, and this fact may be of service in some instances.

In prurigo, a nonvesicular condition, there is also eosinophilia.

In pemphigus and in mycosis fungoides there is often an altered white cell count, but the changes are not constant and have no great diagnostic value. In a large series collected from the literature, the eosinophile count has been found to vary from zero to nearly 50 per cent. In mycosis fungoides much more dependence can be placed on the histologic findings than on the blood picture.

Efforts to separate eczema into allergic and nonallergic groups by means of differential counts seem to be unsuccessful. Hazen² notes a slightly higher percentage of eosinophiles in allergic diseases than in others, but the findings are not constant. Schamberg³ found normal counts in a number of chronic, extensive, severe eczemas. He does not agree with the opinion of Canan,⁴ the German investigator, that eosinophilia is largely proportionate to the extent, intensity, and chronicity of the skin involvement, rather than to any special characteristics of the skin eruption. Canon's opinion has been widely held by dermatologists and it may be worth while

to state that there is very little evidence to support it

The whole question of eosinophilia seems unsettled. It occurs in prurigo and is absent in pediculosis corporis, two conditions that are highly pruritic. It is found in certain animal parasitic conditions and absent in others. Dr Howard Craig, in a personal communication, told the author of a family of eight children, all of whom are well and have been observed for years. The four older children have lived in the tropics and all have marked eosinophilia. The four younger children have normal blood pictures. They have never been in the tropics. The older children have been exhaustively studied at the London School of Tropical Medicine without disclosing any explanation for their eosinophilia.

The eosinophile cells have been studied by many investigators in the hope of establishing their diagnostic importance. Very little has resulted. Some facts have been established but their significance is not yet understood.

The eosinophile cells belong in the granular group of leukocytes and are the most fragile of the group. They originate in the bone marrow, and when they proliferate in large numbers, bone marrow fat decreases and is replaced by cellular elements. The granules in the eosinophile cell contain iron. In certain of the anemias it is thought that some of the hemoglobin lost by the erythrocytes is taken up by the polymorphonuclear neutrophils and that this causes a change in staining qualities so that they may be mistaken for eosinophiles. Eosinophile cells tend to accumulate in the mesenteric glands during digestion and in trichinosis. They are present in large numbers in the lesions of Dühring's disease, prurigo, and sometimes in mycosis fungoides. The ingestion of camphor, cinnamic acid and iodine, and injections of tuberculin cause eosinophilia.

In an individual case there is great variation in the eosinophile count from time to time. The eosinophiles in acute infections aside from scarlet fever, are diminished or absent in the early stages and increase with the lymphocytes as improvement begins.

In spite of the negative findings reported by the older investigators, evidence is accumulating that in the chronic infections—syphilis, tuberculosis and leprosy—something may be learned at times from repeated differential counts. Thus, it is

claimed that in lupus vulgaris, lupus erythematosus of tuberculous origin, early syphilis, and leprosy a study of the monocyte-lymphocyte ratio has prognostic value. An increase in the lymphocytes and a decrease in the monocytes accompanies improvement, whereas increasing monocytosis with lymphocytopenia indicates extension of the disease. This monocyte-lymphocyte ratio is thought to bear a relation to effective treatment.

In tuberculosis, neutrophilia, which always accompanies the acute miliary type, is an unfavorable finding, whereas lymphocytosis is a good one.

Eosinophilia, which may be marked after tuberculin injections, is considered a favorable finding in tuberculosis. In syphilis a sudden increase in the eosinophiles during treatment is said to precede the appearance of exfoliative dermatitis. In all of these chronic diseases monocytosis is present when the disease is active and diminishes as latency or cure approaches.

CONCLUSIONS

1 The differential study of the leukocytes is of limited usefulness in skin diseases. When undertaken at all, a number of examinations should be made.

2 The total leukocyte count is increased only in the leukemias, pyoderma, erysipelas, the exanthemata, the pemphigus group, erythema multiforme, and some cases of mycosis fungoides.

3 The basophiles are increased only in urticaria.

4 Eosinophilia is occasionally of diagnostic significance in scarlet fever, and is often present in urticaria, dermatitis herpetiformis, prurigo, erythema multiforme, pemphigus, mycosis fungoides, and chronic skin infestations.

5 Except in the leukemias, the lymphocytes show no marked changes in dermatoses.

6 The monocytes are increased in early syphilis.

7 The monocyte-lymphocyte ratio has a prognostic value in certain cases of tuberculosis and of leprosy.

8 The interpretation of abnormal findings must be modified to allow for physiological variations in the blood picture, and for possible undetected pathological states unrelated to the skin condition.

ABSTRACT OF DISCUSSION

DR. HOWARD FOX: As the speaker states, the results of leukocytic investigations in skin diseases show considerable variation. One difficulty, I think, is that these studies have been spread over too large a number of skin diseases. There has not been much intensive work, with repeated leukocyte counts on a few dermatoses, based on recent classification of these cells.

The value of leukocyte counts is either for diagnosis or prognosis, and in no case except the leukemias is this very great. The speaker says the leukocyte count has been considered helpful in the diagnosis of scarlatina, a disease whose clinical appearance is at times extremely atypical and difficult to recognize. I have also been informed that little or no attention is paid to this so-called diagnostic point at the Willard Parker Hospital. Both pemphigus and erythema multiforme show a total increase of white cells which unfortunately does not help in differentiating these affections, as at times they resemble one another closely. In regard to mycosis fungoides I think it is generally agreed, that this disease presents no characteristic blood picture, though may at the eosinophile count times be increased.

Eosinophilia, it has often been stated, is a feature of itching skin diseases in general. Schamberg and Strickler have found this to be present in over 80 per cent of cases of scabies. No one, however, would think of basing a diagnosis of scabies on the eosinophile count. There is no doubt that many cases of Dühring's disease and of prurigo show an increase in eosinophiles. As the speaker has said, eosinophilia is lacking in pediculosis corporis, which as we all know is the most pruritic of all skin diseases.

In comparing the blood changes in human and experimental syphilis, Rosahn and Pearce⁵ found a close resemblance. In human syphilis, treatment causes a fall in the monocyte count, and a rise in the lymphocytes. The same thing happens in experimental syphilis in rabbits when spontaneous regression, without treatment, takes place.

Finally, I should like to mention the occurrence of leukopenia in lupus erythematosus disseminatus. Mook, Weiss, and Bromberg in reporting extensively on 13 cases of this disease concluded that leukopenia was an important diagnostic symptom. They stated that this had been mentioned by other writers, but that it had not been sufficiently stressed as a diagnostic point. My experience certainly bears out the contention of Mook and his coworkers in this regard.

In this age in which so much is being said about the high cost of medical care it behooves us to save our patients unnecessary expense by lessening the number of some routine laboratory procedures including leukocyte counts in diseases of the skin.

THE MODERN PHYSICIAN'S WIFE

Being a physician's wife is really a profession in itself, although it has never been listed as such, said Mrs. J. I. Greenwell, President-Elect of the Woman's Auxiliary of the Kentucky State Medical Association, in responding to a toast at a banquet of the Kentucky Pioneer Memorial Association. It is a hard profession, too, she continued, an exacting one, in fact, a delicate calling. In this profession, we are expected to use our own mental powers and, yet, hold our tongues. Yes. We women do talk a lot. But, we never tell all we know.

Aside from our duties to God, to our Church, and other organizations, may I mention the insistent telephone and doorbell! These often call for quick thinking and sometimes I long for "second sight." Midnight calls for the doctor mean midnight calls for us, as well. Every wife must see if her hubby has his rubbers when it is raining, and his overcoat if stormy, and countless other necessities for his comfort and well-being. And, do we not assume, also, burdens of anxiety and worry over the dangerously ill patients in our attempt to lighten the load on the doctor's shoulders and show him our sympathetic interest? Stories, sentimental and cynical, have been

written about the doctor. But—where is the story about the doctor's wife? No history or glorification has been accorded the doctor's help-mate, yet, many times have her gallant service and heroic acts been the means of saving life. The doctor has been canonized on canvas and in bronze. Hospitals, parkways, boulevards, and libraries have been dedicated to him; poets and philosophers have, in rhyme and prose—sometimes in lumbering language—made him a little more than a mortal and a little less than a god. And rightly so, he deserved all the recognition we can give him for his good work. But, what of the doctor's wife? She is not written in song and story; she is not commemorated. Yet, her life, too, is consecrated to service and, inevitably, she sacrifices much, not of her personal comfort and pleasure, alone, but also the sacrifice of her husband's counsel and help so needed in the care of their own children and of their own home affairs while he attends to the wants of his patients.

Without reward, without professional recognition, the doctor's wife stands by him, and by his profession, tugging, lifting, straining, comforting, urging on higher and higher for greater service.

UNDULANT FEVER—DIFFICULTIES IN DIAGNOSIS AND TREATMENT

A Preliminary Report of Fifty-one Cases

HAROLD J. HARRIS, M D

Westport

A small percentage of medical men recognize the true importance and prevalence of undulant fever. It is probable that only a fraction of the existing cases are diagnosed. Few communities are taking measures for its prevention. Textbooks still are publishing inadequate treatises on this subject, describing usually the cases with obvious symptoms. Diagnosis and treatment receive little attention. It is still common to hear otherwise competent physicians state that very few cases of undulant fever exist or that it is a self-limited disease, running its course in a few months or a year at most.

For years, scientific journals have been publishing occasional articles on Mediterranean fever, Malta fever and goat fever. The very titles have largely defeated the purpose of the articles since busy practitioners must necessarily omit from their reading such topics as may sound irrelevant. *B. abortus* infection in man or undulant fever would seem more descriptive, preferably the former since it covers all its manifestations. The work of Bruce, Bang, Evans, and others has been reviewed repeatedly in these articles, but little of the pressing nature of the menace of this disease has been stressed.

Since many physicians are unaware of this situation, public health measures lag.

A large city may have had a pasteurization ordinance for years, but its suburb may have continued to allow the use of raw, potentially infected milk. Physicians especially in these cities, are prone to forget that the disease exists, much less realize its constant increase.

B. abortus infection in cows, goats, swine, and other domestic animals has finally spread to all parts of the United States. Infected cows are disposed of by their owners and, knowingly or otherwise, are re-sold by cattle dealers in various regions, creating new foci if none already existed.

From within a radius of forty-five miles of this small rural community, 51 patients with *B. abortus* infection have consulted

the author within the past eighteen months. Some of these cases had been seen previously but had not been recognized as undulant fever. It is obvious that many other cases exist in patients not ill enough to cause them to consult a physician or in those whose symptoms have been wrongly diagnosed when seen.

The *symptomatology* is so varied that no concise description is possible. *No two patients that the author has seen have had symptoms nearly identical.* They may be so slightly ill as not to seek medical advice for years, or they may be as ill as with severe typhoid. The onset is usually insidious, giving little or no clue to the date of infection.

The usual onset, if the term should be used at all, is with fatigue, malaise, headache, and backache, which the patient (and often even the physician) is apt to ascribe to "overdoing," mild "grippe," or what not. A few patients may have no further symptoms, but repeated relapse is the rule, with more or less complete remissions. Relapses may become more and more severe, occasionally finally resulting in an acute severe illness resembling pneumonia, influenza, malaria, tuberculosis, typhoid fever, or an acute abdominal condition. In some cases the first symptoms noted are of rapid onset with high fever, prostration, and chills. Fever is usually low-grade in the mild relapses (99° to 100° F.), but it may be very high during the relapses in the severe form, ranging to 105° or even higher. Other symptoms occur in a multitude of combinations, usually the same in each relapse but sometimes with added symptoms or a totally different syndrome. Among the often encountered subjective complaints are: chilliness or chills, sweating, "indigestion," flatulence, constipation, nausea, vomiting, nosebleed, joint and muscle lameness and pain, pain in various parts of the abdomen and pelvis, pleuritic chest pain, sore throat, hoarseness, cough (usually brassy and unproductive), dysuria, loss of weight, anorexia, skin eruptions, palpitation, and dyspnea. Remissions

are often not complete, fatigue, slight fever, and vague symptoms persisting throughout the intervals between relapses. Pregnant women may abort.

Objectively little may be found, and thus a neurosis may often be suggested. Pallor when present is a striking symptom since it may occur with or without a concomitant secondary anemia. Pyuria is present in most patients presenting a urinary tract involvement. There is usually a moderate, leukopenia, with relative lymphocytosis. Dental x-rays might reveal one or more apical abscesses in otherwise healthy, vital teeth. Radiography of the gallbladder may reveal poor function in those within symptoms referable to the biliary apparatus. Myocardial involvement may be evident in old, severe infections. The spleen may be enlarged. The skin eruption when present may even suggest scabies.

It is often because of the negative findings that attention is directed toward the possibility of undulant fever. Usually what physical findings there are do not fit in with the tentative or working diagnosis. No matter what illness is simulated, careful study will result in the feeling that it is a peculiar syndrome, not actually identical with the usual picture of any illness.

In nine cases the author was asked to see the patient because the patient or family considered the illness gripe; but in every instance the symptoms were not like the usual gripe. In some, the patient was not nearly so ill, subjectively or objectively, as the height of the fever would indicate. In others the clue lay in the peculiar chilliness or mild chills, accompanied by a disproportionately low-grade fever and the profuse sweating, independent of fever. In several cases the patients remarked that it was a queer kind of gripe they were having. The cough was severe and either totally unproductive or yielding a frothy expectoration. In one patient, (C. C., age 49) seen during a relapse, the first attack of "gripe" had lasted eight weeks, the attending physician having attributed the continued fever and sweating to bronchitis, to pneumonia, and finally to abscessed teeth. Ten abscessed teeth had been extracted.

The *acute abdominal symptoms* are the most worrisome to the physician since perforated ulcer, appendicitis, acute cholecystitis, or salpingitis may be so closely simu-

lated as to make early operation seem imperative.

One such instance was a young man (E. S., age 25) who had consulted the author complaining of a typical duodenal ulcer syndrome which had been recurring for four years. Diet had been of no help. Radiographs showed a characteristic deformity of the duodenal cap. Abruptly this patient exhibited a fever of 103° F., but he was not so ill as to prevent his coming to the office with it. This suggested the advisability of a blood agglutination test, but the next day he was so acutely ill with agonizing diffuse abdominal pain and exquisite tenderness that it did not seem possible to await the blood report. Temperature ranged to 105.6° F. *Laparotomy was not done because there was no rigidity.* The blood agglutinated in a dilution of 1:1200 and the attack lessened in severity. The total duration of fever was ten weeks. He had several abscessed teeth. Intravenous typhoid vaccine and intravenous neoarsphenamine had no effect. Improvement was striking following vaccine therapy, given at intervals over a period of a year. Agglutination in a dilution of 1:40 was recently reported, the titer having gradually declined throughout treatment.

Nosebleed, frequent, profuse and recurrent, over a period of nine years, was the complaint which brought to the office a young man of 22 (H. H.). Physical examination was negative except for a mild secondary anemia, apparently due to repeated blood loss and a temperature of 99.2° F., not accounted for. Within two weeks of this first consultation, the patient returned, complaining only of severe headache and constipation of a week's duration. Temperature was 104° F. Blood agglutination occurred in a dilution of 1:2500. Prostration, headache, backache, and high fever varied in intensity for the next twelve weeks. All his teeth were ultimately extracted because of multiple alveolar abscesses and an advanced pyorrhea. Intravenous typhoid vaccine and intravenous neoarsphenamine had no effect. Improvement has been marked following prolonged repeated courses of vaccine. Agglutination titer is now 1:40 and the patient seems well.

Intestinal symptoms, ushered in by a convulsion, and followed by a severe colitis (diagnosed as such) occurred in a female patient of 62 (H. M. B.), fourteen months before first seen by the author. After gradual improvement a second similar attack had occurred three months later, and again was followed by slow recovery. At that time all twenty-eight, apparently healthy teeth were found to be abscessed and were extracted, complete recovery then being predicted. Continued flatulence, constipation, meteorism, distention, recurrent faintness, loss of weight, and anorexia caused her to seek other aid, nine months after the second acute attack. Physical findings were entirely negative except for abdominal distention and low-grade fever. Radiographs showed a gas-filled, imperfectly outlined ascending colon and imperfect visualization of the gallbladder. Pallor was extreme, but there was no anemia. Blood agglutination for *B. abortus* infection was negative on two occasions. No diagnosis seemed to fit. A skin test, using the method and material supplied by Yeckel and

Chapman, was then done and was violently positive, causing lymphangitis, axillary adenitis, fever, malaise ultimate local sloughing, and marked intensification of previous and existing symptoms. The administration of *B abortus* vaccine at intervals for the past six months has been followed by apparent cure.

Arthritic symptoms of the rheumatoid type in a woman of 49 (J E), had followed an atypical so-called 'grippe.' Blood serum showed a trace only of agglutination with *B abortus*. Treatment using intravenous streptococcus vaccine (after Clawson and Wetherby) was followed by improvement but relapses occurred repeatedly. Subsequent blood sera agglutinated in a dilution of 1:10, 1:10 and ultimately 1:20. Constant improvement and no relapses followed *B abortus* vaccine.

Low grade fever, pallor, and chronic nephritis (albuminuria and casts) occurred in a female child of five (A H), whose only subjective symptom was infrequent recurrent fatigue for about a year. Two blood specimens showed no agglutination with *B abortus*. A skin test showed a delayed positive reaction at the end of seven days. All symptoms disappeared after a short course of *B abortus* vaccine. She is still well six months after termination of treatment and has gained ten pounds.

Recurrent urinary tract infection, with pyuria, low grade fever, malaise, headache and backache, in a woman of 31 (Mrs W S), was observed by the author over a period of eight years. Repeated cultural examination of the urine, guinea pig inoculations and cystoscopy with radiography had yielded no information. Undulant fever had not been considered. A blood agglutination with *B abortus* in a dilution of 1:10 and a week later in a 1:20 dilution recently confirmed the patient's own suspicions. Treatment with *B abortus* vaccine is being carried on, prompt improvement having followed its inception.

Repeated spontaneous abortions occurring in a woman of 29 (R T), who had never been acutely ill ultimately led to a diagnosis of *B abortus* infection. The first fetus, age 6 months, seen by the author was macerated, and the placenta showed macroscopic areas of calcification. The second fetus, also aged 6 months, lived a few hours. The placenta was necrotic with numerous areas filled with decomposed blood. It was inadvertently destroyed. Profuse uterine bleeding, lasting six weeks after each abortion, was terminated after curettement in both instances. Malaise, fatigue, secondary anemia and pleuritic left upper chest pain occurred at intervals, with a low grade fever. A mal-odorous, profuse, purulent vaginal discharge with right lower quadrant pain and a palpable tender tube, followed the second abortion. *B abortus* was isolated from the discharge. The blood agglutination titer was 1:160. There were several abscessed teeth and grossly infected gums. Treatment with several prolonged courses of *B abortus* vaccine and pelvic diathermy has resulted in an apparent cure after ten months. Blood agglutination last occurred in a 1:20 dilution. Cervical secretion now shows no evidence of *B abortus* on cultural examination and guinea pig inoculation.

Headache, backache, fatigue, constipation, and

pelvic pain, brought in a woman of 25 (Mrs V L) for consultation. Low grade fever was the only finding. Five blood specimens taken within three weeks showed a rapidly increasing titer: negative, trace, 1:10, 1:40 and 1:320. Apparent cure followed a short course of *B abortus* vaccine.

Diagnosis was made usually by the standard blood agglutination test. However, blood agglutination is negative in many instances early in the disease, and in a few cases, even after months or years of recurrent illness. *Low agglutination titers (1:10, 1:20, or 1:40) are of as much diagnostic significance, in patients who present a clinical picture of undulant fever, as is the so-called characteristic agglutination in dilutions of from 1:80 to 1:2500.* In the acutely developing disease, an early negative agglutination is usually followed by a steadily mounting titer within a few days or weeks. Repeated agglutination tests are essential in these cases.

In doubtful cases the skin test is of great value. It is often positive, occasionally reacting very slightly and rarely violently, in patients whose blood may show no agglutination even over a period of years. Rarely both blood agglutination and skin test may be negative in the presence of active *B abortus* infection. In these instances when diagnosis is still in doubt, a therapeutic test may be resorted to in the administration of a moderate dose of *B abortus* vaccine. A local and general reaction, with accentuation of existing symptoms, is indicative of probable *B abortus* infection.

It must be borne in mind that subsequent blood study, after skin test or administration of vaccine, may be relatively valueless since agglutinins may be so stimulated, the blood subsequently showing a low titer (1:10 or 1:20). Repeated blood study, therefore, always should precede these latter procedures.

Skin tests should not be done in patients previously treated with *B abortus* vaccine, as violent reactions and local skin necrosis may occur.

Treatment with *B abortus* vaccine has been the only method showing real promise in these cases. Other methods commonly suggested failed to give noticeable results, apparently having been favorably reported on by various workers after insufficient time had elapsed to determine if relapses were to occur.

Early infections appear to yield readily

to vaccine therapy. Older, chronic infections respond more slowly, but persistence in treatment is usually rewarded. Removal of accessible foci of infection, such as infected teeth, may prove essential.

In regions where the source of infection is only from cows infected with *B. abortus*, there seems no reason to use a mixed vaccine (or filtrate) of *B. abortus*, *B. melitensis*, and *B. suis*. Reactions may be unnecessarily severe. Straight *B. abortus* vaccine, prepared by the Division of Laboratories and Research of the New York State Department of Health (2,000 million killed organisms per c. c.), was employed in all cases, except one. This patient received two intravenous doses of typhoid-paratyphoid vaccine, soon after the onset of symptoms and is still well at the end of nine months.

Dosage of vaccine, frequency of administration, and total number of injections should vary with the individual case. The acutely ill patient does not tolerate any but the smallest amount of vaccine without severe or even violent reaction and should, if circumstances warrant delay, have no vaccine until the remission begins. The chronic case will tolerate an average initial dose (0.1 to 0.25 c. c.) with slight or moderate reaction. Subsequent dosage depends upon the severity and duration of the reaction from the previous dose. The interval is usually three days and not more than seven. Longer intervals often are followed by preventable relapse, at which time the administration of a slightly larger dose of vaccine (or, indeed, any dose in some instances) may precipitate extremely violent symptoms. The usual increase is from 0.05 to 0.15 c. c.

Chronic, long-standing cases may require much larger doses than the average full dose of 1 c. c.

Moderate reactions are apparently desirable, especially in long-standing stubborn cases where there may be assumed to be foci of infection in tissues not easily influenced by stimulation of antibodies.

Relapse often occurs during treatment or after it has been discontinued and is usually attended by a sharp rise in agglutination titer which subsequently falls as improvement again occurs (either spontaneously or under resumed vaccine therapy).

Prognosis seems excellent in early infections and apparently good in long-

standing infections if treatment is persisted in. Forty-five patients have been discharged as apparently cured after a minimum of six weeks and a maximum of ten months of treatment, and have remained well for periods up to one year. These all were patients who had relapsed frequently, over periods of from a few months to three years, before treatment was begun. Response to treatment was so uniform as to preclude the possibility of spontaneous improvement.

The remaining cases were of long standing before treatment was begun, the history in some indicating five to ten years of infection and in one of probably 19 years' duration. These patients have all improved markedly under treatment, some relapsing even during treatment, but in no case has the relapse been as severe or as prolonged as before treatment was instituted. In every case the patient reports great subjective improvement. A few of them have been under treatment for over twelve months and still show clinical and serological evidence of continued infection—but these, too, are greatly improved. There is usually a gain in weight as improvement continues.

The *criteria of apparent cure* have seemed to be: (1) clinical recovery (absence of fever, symptoms and signs over a period of months); (2) no general reaction to repeated maximum dosage of vaccine; and (3) a definitely lowered agglutination titer (usually 1:10 or 1:20, following previously higher titers). If all these conditions are fulfilled it seems justifiable to consider the patient well, but also to urge prompt return to observation at any recurrence of symptoms. Spontaneous recovery may occur in an undetermined percentage of cases.

Reinfection seems possible especially in veterinarians and others repeatedly coming in direct contact with virulent organisms.

Semi-invalidism may result in patients who are not treated successfully or in whom the condition is undiagnosed.

Statistics show a mortality of 2 to 3 per cent, perhaps reducible by early diagnosis and treatment. There have been no deaths in this series.

SUMMARY

A résumé of fifty-one cases of undulant fever seen in general practice is reported.

Some symptoms and signs seemingly not widely known, are mentioned. The fre-

quent occurrence of alveolar abscesses in patients with undulant fever is noted

Syndromes such as of duodenal ulcer, and cholecystitis are discussed, in cases confirmed by radiography and subsequently shown to be due to *B abortus* infection

Diagnosis in the various stages and gradations of the infection is stressed

Treatment is discussed, stressing the apparent value of *B abortus* vaccine

CONCLUSIONS

1 The symptoms and syndromes occurring in *B abortus* infections are manifold

2 Many cases are overlooked or wrongly diagnosed, possibly resulting in semi-invaldism or death

3 The incidence of undulant fever throughout the United States is much greater than commonly supposed

4 A negative blood agglutination does

not rule out undulant fever, early or even late in the course of the disease

5 Agglutination in a low dilution of the blood serum (1 10, 1 20, or 1 40) may occur in the presence of active *B abortus* infection early or late in the course of the disease

6 Agglutination, usually in a low dilution, may occur and persist in patients who have apparently recovered from the disease

7 Skin tests are of diagnostic value in doubtful cases

8 Alveolar abscess occurs frequently in the course of undulant fever

9 Repeated blood agglutination tests during and after vaccine therapy are of value as criteria of progress in treatment

10 Vaccine therapy, using the proper strain of organism, gives promise of cure in a large percentage of cases

SMALLPOX GROWING SMALLER

There was less smallpox in the United States and Canada in 1933 than ever before, and if we may judge by the records for seven months of 1934, there will be a further drop this year, in the opinion of the *Statistical Bulletin* of the Metropolitan Life Insurance Company. These seven months not only show a new low record for the period, but report less than one tenth the number of only four years ago. The fight on smallpox seems nearly won.

Some states however, still have a bad record, for 4,589, or 75 per cent, of the 6,122 cases reported by 46 states occurred in 12 states that contain only one fifth of the country's population. Popular sentiment in these states is against vaccination.

Contrast with these ten other states and the District of Columbia, along the Atlantic seaboard, which had only 4 cases of smallpox in 1933, and only 809 in the last three years. The 12 states with high smallpox records are California, Colorado, Idaho, Iowa, Montana, Nevada, Oklahoma, Oregon, Texas, Utah, Washington, and Wisconsin. The ten states with low records are Delaware, Florida, Maine, Maryland, Massachusetts,

New Hampshire, New Jersey, New York, Pennsylvania, and Rhode Island. There is no reason to doubt that the fine record of the ten states could be duplicated by the rest of the country.

In continental Europe, where compulsory vaccination is generally accepted and practiced, smallpox has practically disappeared from all of the countries, excepting Russia and the Iberian Peninsula. In 1931 there was not a single case of smallpox reported in Belgium, Bulgaria, Scotland, Germany, Italy, Luxembourg, Norway, Sweden, Switzerland and Yugoslavia. Only one case each was reported in the Netherlands and Latvia, 5 in Finland, 12 in Greece, 13 in Roumania, and 14 in Poland. France, with a population of over 40 millions, reported only 162 cases.

In England and Wales, on the contrary, where since 1907 'conscientious objectors' have been exempt from compliance with the vaccination laws, the incidence of smallpox has reached such proportions that in 1931 there were reported 5,665 cases, a number far in excess of the total number of cases reported by the whole of continental Europe, excluding Russia.

Normal babies should double their birth weight in five months, physicians say, but the Dionne quintuplets, premature by two months, have done far better than that, according to a report in the *New York Times*. On their five months birth

day all five sisters were more than four times as heavy as when first accurate weights were taken. Their total weight then was only 10 pounds, 1¼ ounces. At the end of five months it was 45 pounds, 10 ounces.

TISSUE REACTIVITY TO STREPTOCOCCI AND ITS BEARING UPON THE PROBLEM OF ARTHRITIS

CHARLES H. HITCHCOCK, M.D.

Syracuse

The treatment of rheumatic diseases has long been a problem to tax the ingenuity of the profession. Much good has been accomplished by the removal of obvious foci of infection, together with the exhibition of antirheumatic drugs and the adoption of measures designed to promote the general health of the patient. Often enough, however, the disease has progressed to varying degrees of permanent crippling before finally becoming inactive. Such results, particularly when affecting those in the earlier decades of life, are deplorable in the extreme, and any method which might offer hope of their prevention would, if proved efficacious, be of considerable value.

The problem of rheumatic diseases has been approached from many different angles, and frequently the experimental results have conflicted to an extreme degree. One need only mention, for example, the inability of most trained investigators to confirm the claims of Rosenow regarding the arthrotropic properties of certain strains of streptococci, or the conflicting results which are still being reported with respect to the incidence of positive blood cultures. In general, however, it may be stated that the evidence which is slowly accumulating stresses with increasing emphasis the rôle of the gram-positive cocci, and particularly of the streptococci, in etiology. By some investigators it has been considered that certain strains of these organisms are specific for these diseases;^{1,2} other workers have either been unable to confirm their results, or have placed different interpretations upon them.

Whether or not specific cocci are concerned, the mode of production of the lesions remains unexplained. Histologically they bear little resemblance to those of ordinary streptococcal infection. This aspect of the matter has recently been subjected to intensive study by workers at the Rockefeller Institute in New York. The problem has been approached by investigating the systemic effects of low-grade

focal infection. A brief description of the results is necessary, in order to clarify the scientific background for the therapeutic measures later to be described.

The repeated intradermal injection of living nonhemolytic streptococci into rabbits results eventually in the appearance of a condition of systemic sensitization to the organism.³ It is, however, necessary that the injections be properly spaced, and that the doses be not too large.⁴ Furthermore, the animal must be treated via the intradermal, subcutaneous, or intramuscular route; intravenous injections have a totally different effect.⁵ Roughly it may be said that the repeated intracutaneous exhibition of these small doses, which need not exceed 0.001 c. c. of culture, is an attempt to reproduce in the rabbit the type of low-grade infection, with streptococci of slight virulence, which is present in human foci of chronic infection. Under these conditions, sensitization to the organism is detectable within two weeks, and after two to three months of continuous treatment reaches a very high level, at which it may be maintained indefinitely. The sensitivity may be detected in several ways: namely, by greatly exaggerated tissue reactions when tiny quantities of culture (e. g. 0.000,001 c. c.) are injected into the skin;⁶ or by the production of fatal shock by intravenous injection of culture in amounts innocuous to normal animals. This condition is not anaphylactic in nature, nor is it dependent upon the presence of antibodies in the serum.⁷ It resembles rather the sensitivity to tuberculin which develops in the tuberculous animal. Furthermore, it is not strain-specific; that is to say, an animal, after receiving intensive treatment with one strain of streptococci, will thereafter show phenomena of sensitivity, no matter with what strain of streptococci it be tested. This is a point of considerable importance.

Let us turn now to the *clinical side*. It has been found that certain groups of hospital patients display a definite sensitivity to streptococci or their products when tested

by intradermal injection of appropriate quantities of vaccine, or of nucleo-protein. This reactivity is in no way comparable to the Dick test. It occurs following recent infection with hemolytic streptococci,⁸ and in addition it is found in rheumatic fever,⁹ glomerulonephritis,¹⁰ and so-called "rheumatic" iritis.¹¹ It is present also to a moderate degree in infectious arthritis, but tends to be weaker in the less acute cases and in those of longer duration. Skin sensitivity alone, however, is not conclusive proof of activity of infection. Let it be remembered, for example, that the intradermal tuberculin test may remain positive after any detectable sign of tuberculous activity has vanished.

There is, however, another method for detecting the sensitivity of infection, namely, the production of systemic reactions. The sensitive rabbit, treated intravenously with a certain amount of streptococcal culture, succumbs within 48 hours, and at autopsy there is evidence of wide-spread endothelial damage. When nonfatal doses are employed, there may be evidence of heightened inflammatory activity in lesions recently produced. Similarly, the tuberculous animal, subjected to excessive doses of tuberculin, dies with marked inflammatory and hemorrhagic reactions about his tuberculous foci. Clinical experience has taught us the ease with which, in human beings, careless use of tuberculin may result in pronounced febrile reactions, with markedly increased activity in the tuberculous lesions, sometimes with disastrous results. These are examples of the induction of focal and systemic reactions in the sensitive animal or patient and are dependent not only upon previous exposure to the organism, but also upon the presence of active or recently active infection.

In a similar manner, focal and systemic reactions may be provoked in sufferers from rheumatic disease, merely by the introduction into a vein of a small dose of streptococcal vaccine.¹² The reactions are evidenced by fever, appearing within a few hours, reaching its peak in from 24 to 48 hours, and then subsiding within a few days, also there was increased swelling and discomfort in joints, and, in the presence of carditis, there occurred gallop rhythm and changes in murmurs. These phenomena are most easily provoked by the use of hemolytic streptococci. The effective dose varies from 10,000 to 500,000 organisms depending roughly upon the severity and

activity of the infection. Conversely, it may be stated that in the absence of recent infectious activity, doses ranging into the millions may be administered without provoking more than the mildest symptoms.

Here, then, there is a condition of focal and systemic sensitivity to streptococci, which up to date has been described only for rheumatic fever, infectious arthritis, and glomerulonephritis. Certain cases occurring in the author's private practice would seem to indicate that eventually "rheumatic iritis" will be added to the list. In other conditions in which skin sensitivity to streptococci is present this more generalized type of allergic reaction cannot be elicited,¹³ and it may therefore be considered as peculiar to the small group of conditions listed. Interestingly enough, it is within this same group that etiological relationship to foci of chronic streptococcal infection has been most strongly indicated upon other grounds.

The existence of this allergic condition having been demonstrated it cannot, unfortunately, be concluded that therewith the whole problem of etiology has been solved. Certain points, however, become more susceptible of explanation. Thus, in the case of rheumatic fever, it has been noted by many observers that the streptococci occasionally isolated are serologically quite unrelated, in fact, two or more totally different strains have at times been isolated in succession from the blood stream of the same individual.¹⁴ Furthermore, the isolations have mostly been nonhemolytic streptococci whereas epidemiological, clinical, and immunological data associate this disease very definitely with *Streptococcus haemolyticus*.¹⁵ At least a partial reconciliation of these difficulties is found in the fact previously mentioned, that in the laboratory animal the allergic state, once highly developed, is not strain specific but can be detected by the use of any streptococcus, regardless of resemblance or lack thereof to the parent strain. The same thing is true in the patient—he reacts to products of hemolytic, green producing, or indifferent streptococci, although most vigorously to those of hemolytic streptococci. It may then be considered, tentatively, that the more virulent hemolytic streptococcus is the primarily infecting and allergizing agent, while the less virulent *S. viridans* and indifferent types assume subsidiary roles once the soil has been prepared.

The allergic hypothesis is of further

value in explaining the extent of the lesions which are found in the more severe cases. At present there is no universally accepted belief in the existence of a constant or severe bacteremia in the rheumatic state. If it be granted that bacteria reach the blood at all, it is probably in small numbers and at irregular intervals. Ordinarily, a few organisms distributed in this manner would be rapidly and efficiently destroyed. However, it has been shown that in the sensitized animal a tiny dose of living bacteria—perhaps as few as 200 or 300 cells—is capable of producing a lesion of a size which in the normal animal, would necessitate the use of at least a thousand times that amount of culture. Comparable conditions presumably exist within the sensitized human being; and, if this be the case, it becomes clear that even an occasional mild bacteremia might easily produce a rather marked tissue reaction. By this is not meant, however, that sensitivity is the *only* factor in the production of rheumatic lesions. It is safe to say that, in spite of a vast amount of experimental work, no one has successfully reproduced in experimental animals lesions histologically typical, for example, of rheumatic fever. It is true that streptococci, from whatever source, will, if used in sufficiently large numbers, eventually produce destructive lesions in the joints of rabbits, dogs, and other animals. Similar lesions may be produced by the repeated injection of small amounts of horse serum into the joints of allergic animals,¹⁶ so that it would seem probable that any irritant, repeatedly injected into a joint, might eventually produce comparable changes. What may be the nature of the irritant operative in the human patient is at present obscure. It seems safe to say, however, that it seldom if ever manifests itself in the nonsensitive patient. In other words, the condition of allergy to gram-positive cocci, and especially to streptococci, is probably an important background for the development of the rheumatic state; and in its absence, such other factors as may be necessary for the production of its peculiar pathological picture are unable to function to that end.

If this be so, it is reasonable to suppose that removal or lessening of the condition of sensitivity might retard the progress of the disease and perhaps lead to its amelioration. The clue to the procedure to be followed must be secured from the laboratory.

It will be recalled that, in discussing the artificial production of sensitivity in animals, the fact was emphasized that cultures must be injected into *tissue*, preferably intradermally. If the intravenous route be employed, no sensitization results, but rather a condition which has been termed "tissue immunity," which in many respects is diametrically the opposite of sensitization. Also, one must not forget that the intravenous injection of sufficient culture into the sensitized animal usually leads to death in shock. It has been found, however, that if very small doses of culture are employed, avoiding shock, and if these are injected intravenously at proper intervals over a sufficient period of time, the condition of sensitization may be removed, and the animal then exhibits the same condition of "tissue immunity" as does the normal animal treated from the beginning by the intravenous route. Such intravenous desensitization is most effectively carried out with the homologous sensitizing organism, though a certain degree of success may be attained by the use of a heterologous strain.

This procedure may be applied to the allergic patient. In discussing the distinction between dermal and systemic allergy, it was pointed out that, in the presence of the latter condition, intravenous injection of a properly chosen vaccine would result in focal and systemic reactions. If the injections are repeatedly made, however, with a constant dose of bacteria, these reactions become progressively lessened in severity, and finally fail to appear. They may then, however, again be elicited by increasing the dose of vaccine. By persistent application of this procedure, it finally becomes possible to carry the intravenous desensitization of the patient to the point where he will tolerate without reaction many times the dosage of vaccine which, in the beginning, caused him severe discomfort.¹⁷ Coincidentally, great amelioration and sometimes complete abatement of symptoms are noted.

It must be emphasized at once that intravenous desensitization is not a procedure which can be indiscriminately applied, and that under certain conditions it is difficult to carry out. These conditions pertain to the presence of untreated foci of infection. In the sensitized animal, the introduction into the tissues of an infected agar focus renders subsequent attempts at intravenous desensitization much less easy of accom-

plishment Following its surgical removal, the animal becomes more amenable to the procedure. Similarly, it has been found that, in the human being, the persistence of untreated or inadequately treated infectious foci adds greatly to the difficulties of intravenous therapy. Such foci must, therefore, be dealt with before institution of biologic measures. To one experienced in vaccine therapy, it is usually possible to decide from the patient's reaction to the initial doses of vaccine whether or not undetected and undrained foci still persist. Likewise, the sudden appearance of intolerance to vaccine, in patients whose previous progress has been satisfactory, has in the author's experience been indicative of the need for renewed attention to some known focus as, for instance, a chronic sinus infection. Firmwork between the internist and the surgical specialist is obviously, then, quite indispensable.

In actual practice, one attempts so to grade the dosage in intravenous desensitization therapy as to avoid focal reactions. This is particularly the case when dealing with ambulatory patients. Such reactions are unpleasant and may at times be of some duration, their net effect is usually to retard greatly the rate of recovery. It is necessary, then, to begin with a dose so small that freedom from reaction seems relatively certain. Often this means an initial injection of a vaccine containing only a few thousand, or even a few hundred, bacteria. Sufficient time must be allowed between treatments to preclude the appearance of a late reaction, for this, five days seems to be the minimum. The dose is carefully raised until an effect is apparent. If this is favorable, the dosage is held at this level and is only very gradually increased. If, however, an unfavorable reaction appears, with exacerbation of symptoms, the dosage is greatly reduced, and then increased with greater caution. As greater amounts of vaccine are administered, longer intervals may be allowed to elapse between injections. It is impossible in a short paper to give exact details of dosage, both with respect to the initial quantity, and the rapidity with which this may be increased. Much, which can be learned by experience only, depends upon the acuteness of the condition, for the more recently an acute flare-up has occurred, the smaller must be the initial dosage of vaccine, and the greater the caution necessary while increasing it.

The question remains as to just what organism should be employed in carrying out an intravenous desensitization. This is a matter as to which there is as yet no unanimity of opinion. Naturally, one would wish, if possible, to utilize the strain directly responsible for the sensitization. When it is considered, however, that it is quite possible for various strains at different times to play a part in maintaining the allergic state, the detection of the offending organism becomes a rather formidable matter. Certain methods have been proposed, which, unfortunately, require for their execution the expenditure of considerable time on the part of a trained laboratory assistant. Such methods are therefore out of reach of most of us. Furthermore it is not finally established that their use is essential to success. The implication by many observers of the hemolytic streptococcus as the primary bacterial excitant leads to the suspicion that this organism is also the primary allergizing agent. If this be so the use of a suitable chosen stock strain in the preparation of vaccine for desensitization might be justified. The employment of such a stock strain—a hemolytic streptococcus originally isolated from the tonsil of a boy suffering from severe rheumatic carditis—has in the author's experience and in that of others proved beneficial to the majority of patients. Skin tests are first made with measured amounts of this vaccine. In this way a rough idea of the degree of sensitization is secured and some indication of the size of the allowable initial dose is afforded. Carefully graded injections are then given at five- to seven day intervals as previously described. At times, particularly when dealing with active rheumatic fever, it is found advantageous to keep the patient under the influence of an antirheumatic drug during the first part of the course. Such drugs are of considerable value during the period when severe reactions are to be expected, as they have the useful property of minimizing or even inhibiting them entirely. With progressive improvement, the dosage of the drug may be diminished, and finally it may be withdrawn with entire safety.

Desensitization therapy is not, of course, a cure-all. Employed in accordance with the principles enunciated in this paper, it forms a useful adjunct to present methods of treatment, but cannot entirely supplant them. When so employed, and patiently

persisted in over a period which may extend to many months, we may believe, from the gist of clinical reports which have appeared to date,^{17, 18} that such therapy will be found of considerable value in increasing the percentage of favorable results.

204 MEDICAL ARTS BLDG.

DISCUSSION

DR. WILLIAM B. RAWLS, *New York City*: Dr. Hitchcock has presented a very interesting paper and I thoroughly agree with his major points. However, there are a few minor statements which require amplification. I agree with him that the exact pathogenesis of rheumatoid arthritis is still obscure but it is the consensus of opinion that the disease is probably streptococcal in origin, although no one strain or type of streptococcus can be said to account for all cases. We have often found as many as three or more serologic variants in the same patient.

Dr. Hitchcock stated that the phenomenon of hypersensitivity is most easily provoked by hemolytic streptococci. Some recent immunologic investigators have shown that certain reactions with hemolytic streptococci do not occur with patients having rheumatoid arthritis. Our studies would indicate that the cause of this misunderstanding

can be traced to the method of determining hemolysis. Most of these arthrotropic strains produce hemolysis of a suspension of red cells or of the surface of blood agar plates. However, in deep blood agar plates (as pointed out by Brown) some of these hemolyzing strains are of the alpha or alpha-prime type. The green pigment is pronounced in deep or anaerobic cultures, whereas it is almost absent in surface colonies. The strains are, therefore, not hemolytic streptococci but *S. viridans*.

We have confirmed the conclusion of many others that intradermal tests are not as reliable as they were formerly considered. We have discarded their use in our clinic in favor of more specific tests.

Since Swift and Hitchcock showed that repeated small intravenous doses tended to desensitize and, believing that arthritis was best explained on an allergic basis, we began in 1930 to administer vaccines intravenously and to date have treated over 500 patients by this method. A large percentage of our patients have been treated with autogenous vaccines prepared from cultures of various foci.

Our doses of vaccine have been considerably smaller than those advocated by Dr. Hitchcock and others. Two explanations are possible: (1) Our vaccines are phenolized unheated suspensions of toxic strains while theirs are perhaps heated, unselected strains. (2) Although the disease may not be caused by a specific strain, the specially selected autogenous organisms are more likely to be specific and the dose must, therefore, be smaller. The effective dose is inversely proportional to the specificity and toxicity of the vaccine and to the acuteness of the disease. Whatever the type of vaccine, there can be no fixed schedule but the dose must vary from time to time according to the patient's reaction, an effort being made at all times to avoid focal or general reactions. This is extremely important as an overdose of vaccine may retard the patient's recovery for a considerable time and even confine him to bed for weeks.

The desensitization must be carried out over a long period of time and with the utmost care. In the presence of active foci of infection, a patient will get a reaction from minute doses of vaccine. If, after several injections, severe reactions still occur, a focus of infection probably exists and should be sought carefully. After removal of a focus of infection, the vaccine can usually be increased much more rapidly. If a patient is progressing favorably and then suddenly begins to experience reactions even though the dose of vaccine has not been increased, it is likely that he has developed another focus of infection. La Grippe or other intercurrent infections must be ruled out as they may produce the same phenomenon. In an analysis of 200 cases we have noted that about 10 to 20 per cent have shown definite improvement following removal of foci and another 5 to 10 per cent have shown temporary improvement. Not more than 25 per cent of patients with typical rheumatoid arthritis showed improvement after removal of foci, whereas with a combination of vaccine therapy with removal of foci improvement was obtained in 60 to 75 per cent.

Following the removal of foci, there frequently are periods of remissions and exacerbations and,

if vaccine treatment is instituted without delay, there is a greater probability for cure. On the other hand, if this is neglected, in a large percentage of cases the periods of remission gradually become shorter and the periods of exacerbation become longer and more severe until rheumatoid arthritis becomes well established.

We have found intravenous vaccine therapy more satisfactory than any other single method of treatment in rheumatoid arthritis. It does not preclude, however, the use of all the adjunct measures at our command, but it should be the basic treatment. For the past 20 months in our

clinic, we have been doing sedimentation rate determinations and nuclear counts regularly every two or three weeks on every patient getting vaccine treatment. In a recent publication we have shown that these two tests are reliable indices for determining the activity of the arthritic process. If the general trend of the sedimentation rate and nuclear count of each patient is noted over a period of months, in a large percentage of cases there will be observed a very definite reduction in both tests in patients who have had no other treatment and who have had no foci removed for a considerable time before vaccine treatment.

CASE REPORT

PERNICIOUS ANEMIA IN A NEGRO

NORMAN STRAUSS, M.D., F.A.C.P.

and

THOMAS F. V. LA PORTE, M.D.

From the Third Medical Division, Morrisania Hospital, New York City

True pernicious anemia occurring in a negro is very rare. Because of the rarity of this combination we wish to record the following authentic case.

As evidence of the infrequency of occurrence of pernicious anemia in negroes it is of interest to note that of the 8,527 negro patients treated at the Morrisania Hospital since its opening five years ago there is no similar case recorded.

According to Evans,¹ pernicious anemia is very uncommon in negroes. Only 9 of the 578 cases of pernicious anemia admitted at Johns Hopkins Hospital from its opening until December 31, 1922, were negroes. These 9 cases occurred among 34,280 negro admissions during the same period.

Osler² makes no mention of the occurrence of this disease in negroes.

Davidson and Culland³ in their book on Pernicious Anemia state: "It is doubtful if the disease ever occurs in full-blooded negroes."

Cornell⁴ quotes: "From the experience of Longcope of Baltimore and of others, pernicious anemia seldom if ever occurs in a full-blooded negro."

J. B., colored, male, was born and always lived in New York City; his age is 48; he was admitted to Morrisania Hospital, February 8, 1934, and discharged March 29, 1934.

Chief complaints on admission were weakness, loss of appetite, nausea and vomiting, coldness of legs.

Present illness.—The onset dated approximately one month prior to admission. The patient noted that he was unable to perform his usual tasks without becoming markedly tired. With this onset of weakness he began

to lose his appetite. He had lost about 15 lbs. in weight during the past 6 weeks. Concomitant with the above he experienced intermittent attacks of epigastric distress associated with nausea and vomiting. During the past 4 to 5 weeks he was frequently troubled with tingling, prickling sensations and numbness of the toes and fingers and coldness of both lower extremities. He also complained of frequent attacks of diarrhea during the above period of time.

Past History.—Certain salient features are of interest. In 1929 he entered another institution with similar complaints. Because of the predominance of gastric symptoms an exploratory laparotomy was performed but no pathology was found. (We obtained this record from the hospital in which he was operated upon.) In 1932 he had a similar bout of symptoms and returned to the same institution. This time he was treated medically and was discharged as improved after a month's stay in the hospital. He had no venereal diseases.

Physical examination on admission showed a slightly emaciated adult colored male, lying quietly in bed and not appearing acutely ill. The pupils were both equal, regular, and reacted to light and accommodation. Sclerae had a slight icteric tint. Conjunctivae were markedly pale. Mucous membrane of mouth was also markedly pale. *The tongue was very smooth, pale, and showed atrophy of the papillae.* Teeth showed pyorrhea, alveolaris. There was visible pulsation of the vessels of the neck. The lungs were clear and resonant throughout. The heart was not enlarged to percussion. Sounds were of weak muscular quality. There was a systolic

murmur at the apex, not transmitted. The liver and spleen were not palpable. No ascites or masses palpable. No tenderness. An old laparotomy scar was present in the epigastric area. The extremities, both upper and lower, were emaciated. The nail beds were very pale. The knee jerks were absent. Bilateral Babinski with confirmatories were present, more marked on left. Vibratory sense was absent. Abdominal reflexes present.

Laboratory Reports.—The urine was negative except for a faint trace of albumin. The stools were negative for blood and parasites. The blood Wassermann and Kahn tests were negative, the spinal fluid Wassermann negative.

The blood count showed hemoglobin 36 per cent by Sahli, red cells 1,600,000, color index 1.1, white cell count 4,600, with neutrophils 73 per cent, lymphocytes 27 per cent, eosinophiles none. Platelets were 90,000. The blood smear, Giemsa stain, revealed marked poikilocytosis and anisocytosis. Many macrocytes were present, but no nucleated red cells were seen.

Gastric analysis yielded no free hydrochloric acid in fasting contents nor in five fractional specimens taken at fifteen-minute intervals after alcohol test meal. Total acidity ran low, 4 in fasting specimens and after meal 5—4—6—6—10. There were no lactic acid, no blood, and no Boas Oppler bacilli.

The diagnosis, thus far, rested on the asthenia, gastro-intestinal symptoms and achlorhydria, the neurological symptoms and signs, the glossitis atrophica, and the characteristic blood picture.

The course of the disease under liver therapy furnishes further proof of the diagnosis. Daily intramuscular injections of 3 c. c. of liver extract (equivalent to 100 gm. of fresh liver). Diet as suggested by Minot and Murphy with liver, beef or lamb kidney for breakfast, dinner, and supper, was given. Dilute hydrochloric acid and ferric ammonium citrate were also given. The following table shows the characteristic response in red cells, haemoglobin and reticulocytes.

TABLE I

Dates	Red blood count	Hemoglobin	Reticulocytes, per cent
February 8, 1934...	1,600,000	36 Sahli	0
February 10, 1934...	1,780,000	37 Sahli	2
February 12, 1934...	1,800,000	38 Sahli	3
February 13, 1934...	1,900,000	39 Sahli	7
February 21, 1934...	1,940,000	39 Sahli	15
February 27, 1934...	2,160,000	40 Sahli	17
March 5, 1934...	2,800,000	43 Sahli	12
March 11, 1934...	3,250,000	52 Sahli	5
March 17, 1934...	3,900,000	58 Sahli	4
March 20, 1934...	4,100,000	62 Sahli	2

With the blood improvement went a corresponding change for the better in all symptoms. Weight increased from 99 to 115 lbs., gastric symptoms disappeared, paresthesias were greatly improved.

HEALING ON THE WINGS OF THE WIND

Nowhere have the airplane and the radio proved greater boons to the sick than in the great stretches of wilderness in lands like Australia. Not long ago, for example, as reported by the London correspondent of the *A. M. A. Journal*, a woman in a cattle station hundreds of miles from the nearest township was suddenly taken ill. Within thirty-six hours she had been taken 700 miles to a hospital in Camooweal.

This feat was accomplished by the aid of wireless and airplane. When it became apparent that the illness was serious, a girl motored 70 miles to another cattle station, which is equipped with one of the mission's pedal transmitter wireless sets. These sets are an Australian invention and are so simple that no training is required to use them.

A message describing the woman's illness was tapped out on a device like a typewriter, operated by pedals like those of a bicycle. As the operator spelled out each word it was converted into Morse by the machine and automatically

transmitted by wireless telegraphy. The message was picked up at the mission's chief country center at Cloncurry, North Queensland.

A few minutes later listeners at the cattle station heard the voice of the "flying doctor," Dr. J. M. Rossell, asking for more information about the woman.

This was again spelled out on the pedal transmitter. An airplane with a pilot and the doctor on board left Cloncurry for the station where the woman was ill.

On arriving the doctor attended to the patient, placed her on a stretcher in a special compartment of the airplane and flew with her to the hospital at Camooweal, where the operation was performed.

The Australian Inland Mission has twenty wireless sets of the pedal transmitter type at key positions in Northern Australia. This particular airplane has flown more than 100,000 miles for the mission without a serious accident, a remarkable performance considering that it mostly has to land on rough station paddocks.

CASE REPORT

SKIN DIPHThERIA

LEGRAND A. DAMON, M.D.

Pathologist, Craig Colony, Sonyea

Diphtheria of the skin is of such rare occurrence as to warrant the report of a case which occurred at Craig Colony. In reviewing the literature I find that its incidence is less than 1 per cent of the clinical bacteriological cases of diphtheria reported. The bacillus gains entrance to the skin usually through excoriations, erosions, or any of the lesions that will break its continuity. It may be either primary or, as is usually the case, secondary to lesions in the larynx, throat, or

March 4th it had spread to the chin and forehead and nearly completely surrounded the mouth. At this time she was placed in bed, and in order to prevent further excoriations the hands and arms were secured in splints. The eruption resembled impetigo in that there was considerable crusting with profuse purulent discharge. Her temperature varied from 99.8° to 101° F., the latter being the highest point that was reached at any time. The pulse rate was, however, very

Fig. 1

Fig. 2

Fig. 3

nasal mucous membranes. It may take several different forms. The ulcerative type in which there is a tendency to the formation of a membrane, the gangrenous type with extensive destruction of tissue, and another type which resembles various dermatoses such as eczema, impetigo, or ecthyma. Not infrequently diphtheria bacilli are implanted in wounds. Before the discovery of antitoxin there were several cases reported of skin infections in tracheotomy wounds. During the World War a few cases occurred in gunshot wounds.

This patient, Margaret B., age 15, was admitted to Craig Colony, Nov. 11, 1930. Nothing in the history of her epilepsy or previous health had any bearing upon her present illness. On February 20, 1931, she developed a pustular eruption on the left side of the face near the angle of the mouth and the left nares. The lesion was accompanied by more or less itching and she persisted in rubbing and scratching the area thereby causing the infection to spread more or less rapidly. By

significant being invariably from 108 to 130. From this date and until March 27th, a period of three weeks, various local applications including ammoniated mercury, S. T. 37, compound tincture of benzoin, and mercurochrome were used and salicylates and Fowler's solution given internally. There was a gradual spreading of the infection in spite of all forms of treatment. She was observed by nearly all the members of the Colony staff and they were quite agreed as to the diagnosis of impetigo contagiosa. Because of the fact that the usual remedies employed seemed to be of no avail and with the idea in mind of making an autogenous vaccine, several cultures were made on March 27th. Much to our surprise, and probably chagrin, a pure culture of diphtheria bacilli of a virulent type was found. Positive identification of the organisms was made both by staining and cultural characteristics, also the organism was found to be virulent by guinea-pig inoculation and was recovered in pure culture from the dead animal. If any doubts as to

the identification of the organism remained, these were at once dispelled by the clinical improvement which promptly followed the administration of 10,000 units of antitoxin. Within forty-eight hours the induration and redness were subsiding and after four or five days the crusts began dropping off leaving a dark red scar, the latter indicating that true skin had been involved in the pathological process. At the end of a week a second dose of 10,000 units was administered. I might state at this time that although repeated cultures were taken from the throat and posterior nares, at no time were diphtheria bacilli isolated nor did she at any time present symptoms of laryngeal involvement.

Since the true nature of the infection was discovered, photographs were made and at fifteen days' intervals thereafter. Figure 1 shows the lesions at their height. Figure 2 taken fifteen days later shows almost complete disappearance following use of antitoxin. Figure 3 shows scarring which resulted and which persists to some extent at the present time three years later.

My chief reason in reporting this case is to bring to your attention the possibility of diphtheric infection of the skin and to emphasize the importance of making bacteriological cultures on lesions which do not readily respond to the usual form of treatment.

ON RECOMMENDING DRUGGISTS

The success or failure of a medicine may rest in the hands of the chemist who compounds the prescription, and it is a serious question whether the physician should not try to safeguard the patient by guiding his steps to a pharmacist whom he knows to be reliable and skilful. Not all will agree on this, of course, but a medical man writing in *Medical Economics*, Dr. L. J. Sokol, believes that the doctor should either compound his own prescriptions, have them compounded by a chosen pharmacist, or specify several druggists by name as reliable. Most doctors may object to the last alternative, he thinks, but he argues that to specify three or four druggists does not imply the forcing of these druggists on the patient. Most patients you meet are reasonable people; you can talk to them; and if your arguments are sound, they will in all likelihood follow your advice.

After all, you are looking out for the patient's good. Surely it is not too much to ask of the man who has just submitted to treatment at your hands, that he conclude the treatment according to your advice.

In the last analysis, it is the prescribed medicine that will cure him. It is, therefore, of vital

importance that that medicine be exactly what you ordered. The dullest patient will agree that it is futile to attempt a cure with incorrectly followed orders.

You will get the best results by being entirely frank with the patient. Tell him that you are advocating certain pharmacists because you have found them to be reliable and expert. Explain, if it seems necessary, that there is no "bonus" attached in this for you.

Confide in the patient and in his native ability and intelligence to understand you. It is remarkable how easily a matter like this can be explained in a few moments' heart-to-heart talk.

Some practitioners use Rx blanks printed on paper carrying a druggist's letterhead. This is convenient and does well enough in communities where one or, at most, a few outstanding pharmacies are known to the public; but it may seem ill-advised in cosmopolitan areas where there are drug stores on each block.

Whichever method is used, one thing is certain: No conscientious doctor must allow his patient to depart with a prescription without advising him of a good place to have it filled.

BOGUS "WARM SPRINGS CHRYSTALS"

One man has been sentenced to a year in Federal penitentiary and two others are awaiting trial on a charge of conspiring to violate the Federal Food and Drugs Act, by advertising and selling "Warm Springs Chrystal Compound" as coming from the springs of that name in Georgia. As a matter of fact, the "chrystals" did not come from that source at all, but were simply a laxative, composed of Glauber's salts, similar in action to Epsom Salts. The "chrystals"

cost only a few cents a pound; they were sold for a dollar a pound.

Quantities of this compound were seized, because of misbranding under the Food and Drugs Act, at the instance of the Food and Drug Administration. The seizures were made at El Paso, Texas; Oklahoma City, Oklahoma; Los Angeles and San Francisco, California; Louisville and Paducah, Kentucky; Cincinnati, Ohio; and Shreveport, Louisiana.

Dr. Wendell C. Phillips

Organized medicine mourns the loss of a leader. Dr. Wendell C. Phillips is dead.

Joining our ranks in December, 1882, his interest and ability became evident and in 1904 he was President of the Medical Society of the County of New York, then President of the Medical Society of the State in 1911, and he reached the Presidency of the American Medical Association in 1926. In the intervals between the periods when he held executive positions, he filled various chairmanships, and was a Trustee of the American Medical Association. The medico-political career outlined in this sketch of commanding official positions hardly indicates the extent of his activities. In the State Society, he was one of those who helped merge the Medical Association and the State Medical Society. Later, he was instrumental in molding the form of our State Society, helping to create the policy of financial conservatism and supervision by a Board of Trustees. Under his leadership, the scientific sessions of the Society developed into well organized scientific sections. He was an advocate of, and finally helped formulate the present Medical Practice Law which established the Grievance Com-

mittee. He saw the establishment of our House of Delegates into a smooth functioning organization with standing committees who carry on, during the recesses of the annual meetings.

Actively as he was engaged in these quasi-public services, he nevertheless continued working in his chosen medical field. He was an otologist. As such he directed one of the Ear Departments of the Manhattan Eye, Ear and Throat Hospital, and taught as Professor of Otology in the New York Post-Graduate Medical School and Hospital. He was the author of many articles dealing with the technical side of otology, and of a text book on Ear, Nose and Throat Diseases. He held positions of distinction in the scientific world, having been Chairman of the Section of Otology of the New York Academy of Medicine and President of the American Rhinological, Laryngological and Otological Society.

His interest and sympathy with the deafened, led to the formation of the American League of the Hard of Hearing whose President he became, and until his death, this activity largely engaged his attention.

All these activities, were well thought out, and constructive improvements. The medical world in which he worked, is better because he lived and labored.

He was a simple man, of kindly temperament, serene judgment and high executive talent. He was an attractive clinical teacher in Otology, a delightful companion, and a desirable team-mate on a committee.

Every position he held meant to him "a job" to whose accomplishment he bent every endeavor until the project was well under way when he would entrust it to others, while he turned to organize and establish new propositions. No one outside the circles of organized medicine realizes the amount of unremunerated toil, and energy expended in the broader sense, for the public welfare, and in the narrower, for the improvement of the profession.

He died at the age of 77 years. Mentally alert to the end, age seemed not to dim his vigor. His life-work is an ever living example to those of us who were privileged to work with him, of unselfish devotion to duties voluntarily assumed.

A Call for "Intestinal Stamina"

The members of the next Congress have been elected. They are turning their thoughts to the measures expected to come up for their decision in the coming session. One bill reported to be now in the making, or perhaps already written, will attempt to fasten socialized medicine upon the country. An effort will be made by its backers to rush it through the Congress and have it signed by the President before the doctors opposing it can muster their forces effectively. Who can doubt that the vigorous and richly subsidized supporters of state medicine are already at work on the Congressmen, preparing their minds to give quick assent to the legislation as soon as it is presented?

Who will be the natural, logical men to be appointed to the key posts in the new state medical administration, when and if it is set up? Who but the ones who are now so actively, by word and pen, trying to saddle this incubus upon the medical profession? Can we suppose, then, that they are now sitting idly by, letting the Congressmen make up their own minds without assistance? Hardly.

If they succeed, it will be because the doctors make no effort, on their part, to put their case before the members of Congress. A barrage of earnest letters from the physicians, not only of this State but of all the States, to the Congressmen of their districts, starting now, will do a thousand times more good than letters written some months hence, when the measure is actually before Congress and the Congressman, his mind distracted by scores of measures, is receiving bushels of letters on other topics in every mail.

The bane of the campaign against state medicine, so far, has been inaction. Some fine morning the physician may wake up to find state medicine a fact, and he can then take his choice between enrolling in the scheme and spending his days in a medical tread mill, sent hither and yon by political martinets, at less pay than the mechanic gets for doctoring sick motors, or he can stay outside and starve to death. He will have perfect freedom of choice to take either course he wishes.

Right now, however, he has a third choice. He can stand on his rights as a citizen and tell the man who is elected to represent him what he thinks. And this is the time to do it. A semi-medical term in current use is "intestinal stamina," which avoids the name of the portion of the cat that is supposedly used in tennis rackets. If we have that grand old quality that has won so many fights when all seemed lost, why not bring it forward now?

Nor should the profession relax its efforts because of the President's address on November 14th when he spoke of health insurance as something that may come "soon or later on." This phrase was grasped by some Washington correspondents as putting health insurance rather on the shelf for the present. The entire passage in his speech on this topic is worth keeping in mind. He said:

"There is also the problem of economic loss due to sickness—a very serious matter for many families with and without incomes, and therefore an unfair burden upon the medical profession.

"Whether we come to this form of insurance soon or later on, I am confident that we can devise a system which will enhance and not hinder the remarkable progress which has been made and is being made in the practice of the professions of medicine and surgery in the United States."

Immediately, of course, the correspondents hurried to Miss Frances Perkins, Secretary of Labor, and one of the chief backers of health insurance, to ask if the Administration was back-pedaling on this matter. To them Miss Perkins "said that there were, of course, many difficulties in the way of health insurance, including the attitude of much of the medical profession." That is a cheering report, at least, in showing that medical opposition is having its effect. Miss Perkins added that a report from a committee of physicians studying the problem is expected soon, which may report only "progress," but she thought that at least a "start" would be made this winter.

When the enemy shows signs of wavering or indecision, then the wise strategist looses his strongest attack. The wavering

in Washington is a sign that now is the critical moment to charge the enemy lines with horse, foot and dragoons. Determined action in the coming weeks may win the battle.

Medical Practice Changes—Ethics, Never

Right and wrong have a way of remaining ever the same through the whirling centuries of change. Like the rules of health, if you violate them, you will suffer for it. Build your structure, if you like, in defiance of the plumb-line, but it will fall. Build your medical practice, if you will, in disregard of medical ethics, and you will see it end in failure and disgrace.

That, in a nutshell, is the basic thought of the three amendments to the Principles of Medical Ethics adopted by the A. M. A. at the Cleveland session to meet the new methods of practice that are springing up in various parts of the land. We have contract practice of several sorts, hospital practice, university practice, and the employment of physicians by lay corporations, perhaps to benefit the public, perhaps to thimblery doctors and public alike in a dollar-chasing racket.

No wonder the physician is a bit bewildered. He hears contract practice denounced by his brethren in the profession, yet he knows that all business is based on contracts and he can see nothing essentially wrong in them. Neither can the Judicial Council, which framed the new amendments. "Contract practice *per se* is not unethical," says the first amendment. It becomes unethical only when it violates well-established principles familiar to every doctor. Certain features or conditions, if present, make a contract unethical, says the amendment, as, for example:

1. When there is solicitation of patients, directly or indirectly.
2. When there is underbidding to secure the contract.
3. When the compensation is inadequate to assure good medical service.
4. When there is interference with reasonable competition in a community.
5. When free choice of a physician is prevented.
6. When the conditions of employment make it impossible to render adequate service to the

patients. 7. When the contract because of any of its provisions or practical results is contrary to sound public policy."

It is often hard to judge, perhaps, if a certain contract falls within or without these rules, and the amendment wisely concludes that in case of doubt, "the decision as to its ethical or unethical nature must be based on the ultimate effect for good or ill on the people as a whole." Certainly nothing could be fairer than that.

Next we come to the association of a number of physicians in group practice, which has stirred up ill-feeling in many places. What is it that has caused the acrimony and criticism? In nine cases out of ten it is the group's resort to advertising methods and high-pressure salesmanship that not one doctor in the group would ever use in his own individual practice. They forget the simple truth that "the ethical principles actuating or governing a group or clinic are exactly the same as those applicable to the individual," and their union in an organization "does not relieve them either individually or as a group from the obligation they assume when entering the profession." In these clear words the second amendment brushes aside the clouds of doubt, and illuminates the situation with the white light of reason. Anyone who misunderstands matters after this will have some difficult explaining to do.

Worst of all, of course, are the lay organizations of high-power promoters who hire their doctors like factory hands and work them and the dear public for all there is in it. Doctors suffering from the depression are sometimes tempted beyond resistance by the pay-envelopes held out by these concerns. The amendment dealing with this type of practice is outspoken. It reads: "It is unprofessional for a physician to dispose of his professional attainments or services to any lay body, organization, group or individual, by whatever name called, or however organized, under terms or conditions which permit a direct profit from the fees, salary or compensation received to accrue to the lay body or individual employing him. Such a procedure is beneath the dignity of professional practice, is unfair com-

petition with the profession at large, is harmful alike to the profession of medicine and the welfare of the people, and is against sound public policy."

The lure of the unethical is no lure at all, of course, to the doctor who looks three, five, ten years into the future. Any medical organization of lay money grabbers is as certain to get into bad odor with the public as an infected pool in a swamp, and the doctor who is identified with it will never live it down in his lifetime. The new amendments are not preachy, they are merely codified common sense.

Whispers, Whispers, Whispers

"Shall I come home for examination?" telegraphed a young man on vacation in Canada to his father, a well-known New York physician. The boy had heard the rumor that lepers had been discovered working in the plant manufacturing a widely advertised product he had been using. The father, fortunately, had a strong vein of common sense, and wired back: "In my opinion the rumor is a bunch of bunk!" The son continued his vacation.

But how many others were worried into nervous and perhaps physical ills, and how many thousand dollars were lost by the manufacturer whose product was falsely maligned by this whispering campaign? How many other products, too, have been damaged by rumor-mongers who start malicious reports as despicable as a stab in the back?

These questions are provoked by the discovery of a firm in New York City who advertise themselves as "trained propagandists," and contract to "give out information by word of mouth" in "subway, elevated, and railroad trains, street cars, steamboats, office or department-store building elevators," and also at "theaters, concerts, picnics, fairs, baseball and football games, and other events, and places of public assemblage." When questioned by reporters, the firm protested that it circulated no hostile rumors against any product, but only promoted benign propaganda campaigns to benefit the business of its clients.

So we have the business of buying and selling whispers, and, like many other lines

of endeavor, it is up against the rivalry of free competition. No town is too small to have its whisperers, who charge nothing for their work, but who can do more damage than a plague of locusts. Fortunately no village is too tiny, either, to have its spreaders of good reports, its carriers of kindly and helpful propaganda, and it is hardly too much to say that every doctor's success is founded on this basis. It rests on kind words. It is built on whispers—of the right sort.

Here, then, is a subject of vital concern to the physician. If his edifice can be made or unmade by whispers, should he not lay out his campaign accordingly? Why not do a little veiled advertising to help the kind words along, and why not administer a few sharp raps to Dr. X., who is capturing a lot of the local practice? Well, entirely aside from what the Medical Society and its rules may have to say about it (and they will say plenty), our complex human nature is built in such a strange way that efforts to move it this way and that often have results exactly opposite to those intended. Abuse your opponent in a political campaign, and you will elect him. Blow your own horn in a shrill and strident solo, and you only raise a laugh. So the doctor whose name suddenly pops up here, there, and everywhere is apt to arouse a curiosity that is not admiration, and the doctor who raps his brother practitioner will gain nothing by it. The medical rules of ethics are not mere paper regulations, concocted by self-appointed censors of conduct. They are founded deep in the nature of man, and cannot be flouted with impunity.

So even whispers have their place in our scheme of things, to rule our destinies for good or evil, and he who makes his plans without regard for them does so at his peril.

Nurse (in insane asylum): "There's a man outside who wants to know if we have lost any male inmates."

Doctor: "Why?"

Nurse: "He says some one has run off with his wife."

ANNAPOLIS LOG.

We read of a Seattle physician who testified in a suit for a fee for an appendectomy, the patient dying three weeks later, that damage to a doctor's reputation when a patient dies should entitle him to a large fee!

News

of Interest to the Profession

EXECUTIVE COMMITTEE

FEE SCHEDULES AND THE STATE SOCIETY

Because there appears to exist some misunderstanding in some quarters, the Executive Committee issues the following official announcement:

The Executive Committee of the Medical Society of the State of New York calls the attention of the entire membership to the fact that the Society has never in its history adopted, endorsed, or set up any schedule for professional fees for medical service by its members in any field of medical activity. The Society has always taken the stand that arrangements for fees should be considered as personal and private arrangements between individual physician and patients.

AN INVITATION TO BE DECLINED

Recently a letter was received by the President of the Society and referred by him to

the Executive Committee. The letter was from the "Aetna Company" of 1123 Broadway, New York City. It contained an invitation for listing at an annual cost of \$25 "in a physician's addition to the forthcoming issue of our Insurance Directory" which "in its present form contains the names of attorneys in the United States and Canada familiar with insurance procedure."

The Executive Committee disapproves the inclusion of names of members in such a list. The Committee desires to call attention to the apparent similarity in names of the Aetna Company and the Aetna Life Insurance Company, our group insurance carrier. That there be no misunderstanding it is announced that investigation shows that there is no connection between the two companies.

D. S. Dougherty, Secretary

PRIZE ESSAYS

Of the Medical Society of the State of
New York

The Merrit H. Cash Prize and the Lucien Howe Prize will be open for competition at the next Annual Meeting of the Medical Society of the State of New York, May 13, 1935.

The Lucien Howe Prize, of one hundred dollars, will be presented for the best original contribution on some branch of Surgery, preferably Ophthalmology. The author need not be a member of the Medical Society of the State of New York.

The Merrit H. Cash Prize, of one hundred dollars, will be given to the author of the best original essay on one of the following subjects designated by the Committee:

1. Traumatic Surgery of the Hand and Wrist including fractures not, however, of radius and ulna; infections; tendon suture, etc.
2. The relation of Thyroid Surgery to Cardiac Disease.
3. Surgery of the Blood Vessels.

Competition is limited to the members of the Medical Society of the State of New York, who at the time of the competition are residents of New York State.

The following conditions must be observed:

Essays shall be typewritten or printed and the only means of identification of the author shall be a motto or other device. The essay shall be accompanied by a sealed envelope having on the outside the same motto or device and containing the name and address of the writer.

If the Committee considers that no essay or contribution is worthy of the prize, it will not be awarded.

All essays must be presented not later than April 15, 1935 and sent to the Chairman of the Committee on Prize Essays of the Medical Society of the State of New York, 2 East 103rd Street, New York City.

*Eugene H. Pool, M.D., Chairman,
Committee on Prize Essays.*

ANNUAL MEETING OF THE SECOND DISTRICT BRANCH

The Second District Branch held its Annual Meeting on November 15, 1934 at the Garden City Hotel with attendance upwards of 200. At the scientific session in the afternoon twenty speakers presented various aspects in five-minute talks on medicine and therapy in infancy and childhood as follows:

- The Importance of Pre-Natal Care
Walter F. Watton, Brooklyn
- Examination of the Infant Immediately After Birth Luvia M. Willard, Jamaica
- Fever in the Infant Harold A. Butman, Manhasset
- Diet in Infancy and Early Childhood
Kenneth G. Jennings, Brooklyn
- Endocrine Conditions in Children Murray B. Gordon, Brooklyn
- Oral Hygiene in the Child Oscar Rodin, Brooklyn
- Prophylactic Immunization for the Child
Charles W. Martin, Far Rockaway
- Mental Hygiene Sam Parker, Brooklyn
- The Care of the Eyes A Milton Goldman, Rockville Center
- Nose and Throat Care Samuel Zwerling, Brooklyn
- Allergy Henry Straus, Brooklyn
- Examination of the Pre-School Child
Abram S. Tepper, Far Rockaway
- Examination of Children at School
Joseph F. Paulonis, Brooklyn
- Infectious Diseases of Childhood Walter C. A. Steffen, Flushing
- Surgical Problems in Childhood John E. Jennings, Brooklyn
- Syphilis in the Child Thurman B. Given, Brooklyn
- Deficiency Diseases of Infancy and Childhood
Sydney Nussbaum, Brooklyn
- Orthopedic Care Kenneth T. Young, Rockville Center
- Tuberculosis in the Child Henry A. Reisman, Jamaica
- The Nutrition of the Child in the Depression Era
Benjamin R. Allison, Hewlett

The election of officers resulted as follows:
President, Carl Boettiger, M.D. of Flushing.
First Vice-President, Irving Gray, M.D. of Brooklyn.

Second Vice-President, Albert E. Payne, M.D. of Riverhead.

Secretary and Treasurer, Alec N. Thomson, M.D. of Brooklyn.

The Annual Dinner was very well attended and three speakers addressed the gathering. Dr. Frederic E. Sondern, who had just returned from a trip to England, spoke as follows on National Health Insurance in England:

"In the London Times of the 27th of September last, I chanced to read that the Chief Medical Officer of the Ministry of

Health in his recent annual report quoted a very disturbing set of figures relating to time lost to industry through sickness. Among the insured population only, and excluding also loss due to sickness for which benefit is not payable, there was lost in 1933 a total of 29 million weeks work, or an equivalent of 12 months work for 558,000 persons. These figures, states the article quoted, cannot be regarded with complacency. You know the conservative attitude of the London Times. You will also note that there are conditions under which the insured persons do not benefit from such insurance.

"Taking for the moment the relative population of England and the United States, and assuming that the proportion of the members of a possible compulsory health insurance system to the total population would be the same in both countries, what would our figures be? The estimate works out as follows: A loss of 75½ million weeks work through sickness or an equivalent of 12 months work for 1,506,000 persons. While there are no existing figures in this country to verify this or any that would serve for a comparison, it would seem obvious that compulsory health insurance has not aided in the lessening of sickness in industry in England at any rate.

"Interest aroused by these figures induced me to turn to the 15th Annual Report of the British Ministry of Health for 1933-1934. This is a book of some 400 pages. The subject of National Health Insurance forms but a minor part of the report and even so it quotes many conditions and figures of interest to us, particularly in view of the present day agitation for this type of medical care, the more so as they are at considerable variance with those often quoted by the advocates of compulsory health insurance in this country.

"For example, there are 15,150,000 persons at present insured under the system and there are 15,500 physicians who do this type of practice. Thus if each physician has an equal number of patients on his panel, this number would be 970, and with a remuneration of 9 shillings per patient per year the income would be £437 or 2185 present day dollars, but as this amount is now subject to a 10% emergency deduction, it is reduced to \$1,967. Even this amount is not net as it is subject to additional details to be mentioned later to say nothing of income and other taxes. It must not be forgotten that all panel doctors do not have the same number of patients by any means, thus the majority have an income of less than \$1,967 and the minority receive larger sums. This is scarcely compatible with the quoted average of £500 to £600 or \$2,500 to \$3,000 so often mentioned in pro health

insurance talks here. Let us assume that 20% of the doctors do have an income of £600 or \$3,000. What would be left for the remaining 80%—just exactly an average of \$1,700.

"Let me analyze if you allow, some more of the figures quoted in the report, which are instructive to us.

"The Cost of Medical Care is detailed as follows: The total medical benefit cost was £8,420,000 or \$42,100,000. Of this sum the insurance doctors received £6,077,000 or \$30,385,000 divided, as I have stated. The remaining £2,343,000 or \$11,715,000 were allowed as follows: £1,863,080 or \$9,315,400 to the insurance chemists for drugs and appliances, an average of 62 cents per patient per year. The maximum allowable under the rules is 69 cents per patient per year. Even at that, there is a strong paragraph on the investigations of excessive prescribing, and while the accusations were numerous the convictions were few, but amounts as high as \$100 were deducted from several doctors incomes.

"£196,000 or \$980,000 were allowed for medicines supplied by doctors personally and £203,000 or \$1,015,000 were paid doctors on account of mileage to outlying districts—together about \$127 per panel doctor.

RECEIPTS FOR 1933

Contributions (sources not detailed)	£22,020,000	\$110,100,000
Interest and other receipts	4,870,000	24,350,000
Parliamentary votes, grants	5,056,000	25,280,000
Total	£31,946,000	\$159,730,000

EXPENSES

Medical services (Prev. detailed)	£8,633,000	\$43,165,000
Sickness Benefit	9,562,000	47,810,000
Disablement Benefit	5,095,000	25,475,000
Maternity Benefit	1,296,000	6,480,000
Other Benefits incl. Sanatoria	2,204,000	11,020,000
Total	£26,790,000	\$133,950,000

COST OF ADMINISTRATION

Approved Societies and Ins.				
Coms.	£3,923,000	\$19,615,000		
Central Departments	841,000	4,205,000	4,764,000	23,820,000
			£31,554,000	\$157,770,000

"£63,900 were paid on account of insured persons exercising their option to claim treatment through approved institutions, and £7,250 on account of insured persons who were required or allowed to make their own arrangements for medical care. In other words a total of \$355,750 were allowed for the purposes stated. It is not reasonable to suppose that the panel doctor received remuneration for such cases and the deduction of this amount from his income would further reduce it accordingly.

"Finally £9,000 or \$45,000 were set aside for post-graduate study courses. Of this amount only £2,830 or \$14,150 were used in 1933 for this purpose in grants to 102 doctors. This equals \$139 each. Can you visualize what sort of post-graduate course can be had with board and lodging for this sum. Let us assume for the sake of argument that the whole amount of £9,000 or \$45,000 had been used. This would mean a bit over \$29 per year per panel doctor, and each one could thus be entitled to the larger sum of \$145 if he would seek instruction once in 5 years. These figures speak for themselves and I quote them on account of the rosy description of this feature by the proponents of compulsory health insurance in this country.

"It seemed but logical and I hoped that the figures quoted would be followed by equally simple and illuminating ones concerning administrative costs as well as the cost to the employe, the employer and the Exchequer if any, but such is not the case. In fact the quotations in this regard are so involved and include so many other "benefits" that it is quite impossible to figure by itself the net costs of compulsory health insurance which seems unfortunate. You may however be interested in some of these inclusive figures nevertheless.

"I must repeat that it seems strange that the relative cost of administration is not detailed and thus no opinion is justified concerning a total administrative cost of £4,764,000 or \$23,820,000, a goodly sum however even for the inclusive administration of benefits for 15,500,000. This equals £1-6-0 or \$6.50 per head per year.

"Further comment on these figures serves no purpose but visualize for a moment if you will the figures that would be produced by such systems in our country, and the oppor-

tunities offered thereby to lay administrators.

"After all the matter that concerns us most is the quality of the medical services rendered under such auspices. Much has been said and written in this regard, and I can but add that in my experience in England, the insured patient has no regard for his panel doctor and in the event of a serious condition, in his words he secures a "real doctor" if it takes the last shilling he has."

The President of the Medical Society of the State of New York, Dr. Arthur J. Bedell, then delivered an address with the title of *IS THE PHYSICIAN PREPARED?* The full address will be found elsewhere in this issue.

Following this address Mr. Mathew Woll, third Vice-President of the American Federation of Labor, spoke at some length on the subject of *LABOR LOOKS AT MEDICINE*.

Mr. Woll drew both parallels and contrasts between medicine and labor. Both are deeply interested in health. To the laboring man

health is capital because sickness spells loss of power to earn his wage. Both seek to retain the personal relationship between patient and physician.

On the problem of how to secure adequate care and how to compensate the physician labor and medicine are not at present of the same mind. Labor would prefer wages sufficient for each member to compensate the doctor privately. But since industry does not grant this wage, labor must turn to compulsory health insurance, which is not accepted by organized medicine.

In the field of workmen's compensation labor stands for administration by exclusive State Funds rather than through the intervention of insurance companies that must show profit on their operations.

The speaker believed that the closeness of interests of medicine and Labor indicates the necessity for friendly discussion of the question how best to provide adequate medical care to labor and adequate reward to medicine.

DIPHTHERIA CAMPAIGN IN NEW YORK STATE

The *Weekly Bulletin* of the Municipal Department of Health of Albany in its November 8, 1934, issue contributes a most inspiring call to arms that has appeared since the start, last Spring, of the present antidiphtheria campaign. It is here reprinted:

RETROSPECT

Nineteen Hundred, A.D.:

Where are the elves who danced in play
With us, bright-eyed, the other day?
Playmates' quest in sorrow ends—
Where, then, are our little friends?

(Sinister card on the home bereft)
Where were you when the big box left?
Came in the night—took them away:
Thus went the chums of yesterday.

Whisper the word and pass the gate
Stealthily, children—perils 'wait;
Two from this house, one from there.
Lord, not OUR baby—this one spare!

Nineteen-Thirty-Four-Thirty-Five:

Thanks to the toil of folks in white,
Little ones safely sleep tonight.
Mothers need fear no strangling cry;
No more from THAT must baby die.

Arms are ready to kill the foe
But we cannot fight it unless we know.
Have them protected—it is their due,
Fathers and Mothers, it's up to you!

MARY A. O'LEARY.

The *Bulletin* comments on this poem by saying that "The thought expressed will recall to the minds of the older physicians who practiced before 1900 and in the early days of the present century some of the tragic incidents in the experience of the family physician—tragic because there was nothing he could do about it.

The younger generation will never know the trials and hardships which were borne by their predecessors in fighting diphtheria, which were intensified by the frantic fear and uncertainty on the part of the heads of the families. The poem expresses the idea of the scourge from the family standpoint, although it voices thanks of a later generation to those who discovered and made use of the curative and preventive agents which have drawn the sting from the old foe. However, we must never forget those old rugged heroes who bore the brunt of the battle until the weapons were forged with which we are able to accomplish the task. For without the help of antitoxin, toxin-antitoxin, or toxoid they usually fought a losing battle, unless an early intubation was performed.

"We should give thanks that an almost 100 per cent sure way has been found and that is prevention of the malady."

MEDICAL PRACTICE ACT, 1926-1934

HAROLD RYPINS, M.D.

Secretary, Board of Medical Examiners, Executive Secretary, Medical Grievance Committee

Since the investigation and prosecution of illegal practitioners, as well as the work of the Grievance Committee in the discipline of licensed physicians, is largely made possible by the two dollar annual registration fee paid by all physicians to the State Department of Education in accordance with the statute, the following brief summary of the results of these activities should be of interest to all practicing physicians in New York State.

The immense amount of work which has been accomplished in the elimination of illegal medical practice is shown in the following summary of the 3,395 complaints of illegal practice investigated by the Education Department from 1926, when the Medical Practice Act went into effect, until July, 1934.

1934 (to July 1)		1926-1934	
149		1,345	
104		1,488	
91		562	
75	Acquittals	473	
4	Withdrawn	36	
0	Pending trial	41	
12	Cases incomplete	12	
58		
402		3,395	

In the left-hand column the classification of cases investigated is for the current year; in the right-hand column the total cases investigated for the entire period, 1926-1934. The investigation of 1,345 complaints or approximately one-third of those received, failed to show that there was any violation of the law; in 1,488 cases, where a violation was found, such violations were stopped without the necessity of court procedure. These violations were largely of a minor or technical nature.

This leaves 562 cases in which the evidence obtained was sufficient to require legal prosecution. Of these 562 prosecutions, 473, or 84 per cent, resulted in convictions. Only 36 cases, or 6 per cent resulted in acquittals. Forty-one cases were withdrawn and 12 are still pending trial. This represents an extraordinarily high percentage of prosecutions in any type of criminal procedures.

During the period September 1928 to July 1934 the Medical Grievance Committee has considered 397 complaints against licensed physicians, classified as follows

Improper advertising	75
Attempted abortion	47
Aiding illegal practitioners	50
Ambulance chasing	16
Fraud and deceit	40
Malpractice	61
Unethical practice	76
Narcotic violation	2
Insanity	1
Arbitration	3
Miscellaneous	26

Of these 397 complaints, 355 were disposed of by the Grievance Committee (206 by the Secretary, 139 after informal hearing, and 10 after formal hearing). In addition, 26 cases were referred to the Board of Regents after formal hearing by the Grievance Committee. Of these the Board of Regents revoked 11 licenses, suspended the licenses of 6 physicians from six months to two years; ordered formal censure and reprimanded by the Grievance Committee in 8 cases; and dismissed 1 case. There are 16 cases pending.

The work of the Grievance Committee has been of great benefit to the public and the profession. It has protected a large number of physicians from unfounded and unwarranted claims of incompetence, malpractice, and negligence and saved them from unnecessary civil court procedures without any expense or publicity. On the other hand, it has afforded a means whereby the medical profession's high standing is maintained.

Neither the Secretary of the State Board of Medical Examiners, who acts as Executive Secretary of the Grievance Committee, nor any members of the Grievance Committee receive any remuneration for these services.

In general, the amount of money received from physicians' fees, plus fines, approximates the amount of money spent annually for the enforcement of the Medical Practice Act, a small balance being returned to the State treasury at the end of each fiscal year as required by the law.

AMERICAN ASSOCIATION FOR THE STUDY OF GOITER

Prize Essays

This Association again offers its Van Meter Prize Essay Award of \$300, and two honorable mentions, for the best essays on the sub-

ject of goiter that may meet the standards of its award committee. Essays must be based on original research work on the sub-

ject of goiter, preferably on its basic causes. While competition is widely open in world-wide fashion, all members of the Medical Society of the State of New York are eligible as competitors.

In 1934 the first prize of \$300 was awarded to M. A. B. Brazier, Ph.D., B.Sc., London, England, for her essay "The Impedance Angle Test for Thyrotoxicosis." First mention went to Professor Ugo Cerletti, Genoa, Italy, for his essay "Three Years of Experimental Research in the Etiology of Endemic Goiter." Second mention was given to

D. Ray McCullagh, M.D., Cleveland Clinic, Cleveland, Ohio, for his essay "Studies in Blood Iodine using a New Chemical Method."

Competing manuscripts should be in the hands of the Corresponding Secretary, W. Blair Mosser, M.D., Kane, Pa., not later than April 1, 1935. The first prize essay, or its abridgement, is to be presented at the next annual meeting of the Association to be held in Salt Lake City, Utah, in June, 1935, either by the author or a substitute. Publication is left to the author.

A.M.A. SCIENTIFIC EXHIBITS

Application blanks are now available for space in the Scientific Exhibit at the Atlantic City Session of the American Medical Association, June 10-14, 1935. The Committee on Scientific Exhibits requires that all applicants fill out the regular application form and re-

quests that this be done as early as convenient. Applications close February 25, 1935.

Persons desiring application blanks should address a request to the Director, Scientific Exhibit, American Medical Association, 535 North Dearborn Street, Chicago, Ill.

FIRST INTERNATIONAL CONGRESS OF GASTRO-ENTEROLOGY

From August 8 to 10, 1935, there will be held at Brussels, Belgium, for the first time a Congress on Gastro-enterology of international scope. The President of the Congress is to be Dr. J. Schoemaker of the Hague, Holland, the Secretary-General, Dr. George Broh  , Rue de la Concorde 64, Brussels, Belgium. The Congress will assemble under the patronage of Their Majesties the King and Queen of Belgium.

Dr. Max Einhorn of New York City has been asked to form and act as chairman of the North American Committee, and Dr. De-Witt Stetten of New York City has been designated as Secretary of this Committee. A tentative list of members of the North American Committee has been drawn up as follows:

Alvarez, Dr. Walter C., Mayo Clinic, Rochester, Minn.

Andresen, Dr. Albert Frederick Ruger, 88 Sixth Ave., Brooklyn, N. Y.

Balfour, Dr. Donald C., Mayo Clinic, Rochester, Minn.

Bassler, Dr. Anthony, 784 Park Ave., N. Y. C.

Bettman, Dr. Henry Wald, 19 Garfield Place, Cincinnati, Ohio.

Bishop, Dr. Louis Faugeres, Sr., 121 East 60th St., N. Y. C.

Bishop, Dr. Louis Faugeres, Jr., 121 East 60th St., N. Y. C.

Boles, Dr. Russell S., Rittenhouse-Plaza, Philadelphia, Pa.

Brooks, Dr. Harlow, 47 West 9th St., N. Y. C.

Cheney, Dr. William Fitch, Shreve Building, San Francisco, Cal.

Cole, Dr. Lewis Gregory, 36 East 61st St., N. Y. C.

Coleman, Dr. Warren, 875 Park Ave., N. Y. C.

Crohn, Dr. Burrill B., 1075 Park Ave., N. Y. C.

Dube, Dr. Joseph E., 454 Sherbrooke East, Montreal, Canada.

Einhorn, Dr. Max (Chairman), 20 East 63rd St., N. Y. C.

Finkelstein, Dr. Reuben, 576 Eastern Parkway, Brooklyn, N. Y.

Garbat, Dr. Abraham Leon, 113 East 81st St., N. Y. C.

Goldstein, Dr. Hyman I., 1425 Broadway, Camden, N. J.

Graham, Dr. Evarts A., Washington University, School of Medicine, Dept. of Surgery, Barnew Hospital, 600 South Kings highway, St. Louis, Mo.

Hayes, Dr. William Van Valzah, 115 East 61st St., N. Y. C.

Heyd, Dr. Charles Gordon, 116 East 53rd St., N. Y. C.

Horsley, Dr. J. Shelton, St. Elizabeth's Hospital, 617 West Grace St., Richmond, Va.

Jacobsen, Dr. William C., 40 West 69th St., N. Y. C.

Jones, Dr. Allen A., 333 Linwood Ave., Buffalo, N. Y.

Kaufman, Dr. Jacob, 52 East 58th St., N. Y. C.

Kellogg, Dr. Edward L., 43 West 54th St., N. Y. C.

Kelly, Dr. William D., 220 Lowry, Medical Arts Bldg., St. Paul, Minn.

Lahey, Dr Frank H, Lahey Clinic, 605 Commonwealth Ave, Boston, Mass
Lynch, Dr Jerome Morley, 205 East 61st St N Y C
Lyon Dr B B Vincent, 2031 Locust St, Philadelphia Pa
Manning Dr G Randolph 510 Madison Ave, N Y C
Morgan, Dr William Gerry, Georgetown University, School of Medicine Washington, D C
Nichols Dr Bernard H, Cleveland Clinic Euclid Ave at 93rd St, Cleveland, Ohio

Medicolegal

LORENZ J BROSNAN, Esq
Counsel, Medical Society of the State of New York

Responsibility of Physician for Negligence of Dentist

In one of the Mid-Western states, in a recently decided malpractice case* the Court was called upon to decide the extent to which one physician might be held legally responsible for the negligence of another. The fact situation involved is an interesting one, and must be referred to in some detail.

The plaintiff a certain Miss N had been for some time under the care and treatment of a Dr W for pains in her neck, face, shoulder and arm. In the course of the doctor's treatment he had certain x-ray pictures taken which revealed that the patient was suffering from an impacted and impacted wisdom tooth. He determined that it was at least a partial cause of her complaints and told her it should be extracted. A conversation was had between Dr W and Miss N as to what dentist should be employed to make the extraction. One dentist was discussed and his name discarded when Dr W told the patient that that dentist would probably put her to the expense of additional x-rays. The doctor then suggested that Dr S, a dentist, would accept his x-ray and recommended that the patient arrange to have Dr S take out the tooth. Thereupon the latter dentist was consulted and after examining Dr W's x-ray plate, he also advised

the extraction. It was determined that an ether anesthesia should be administered and arrangements were made so that Dr W acted as anesthetist in connection with the operation. According to the story told by the patient and her mother, Dr W was also to "look out for her interests" at the operation.

The anesthetic was administered at about nine o'clock in the morning, and the patient was under its influence for about three hours, and was unable to sit up until several hours later. The dentist upon undertaking the extraction first extracted an adjoining tooth which he claimed it was necessary to remove. Upon attempting the removal of the impacted wisdom tooth, in some manner the patient's lower jawbone was fractured. Upon the discovery of the fracture, Dr S, the dentist, cleansed the wound, and then Dr W stepped in and put the bones in the best alignment possible and held them in that position while the dentist applied a bandage. The same evening the physician applied a leather strap to hold the jaw in place. The physician then took over the care of the case and saw her daily. He changed the dressings, and gave antiseptics to check infection regularly. A week after the operation Dr W took an additional x-ray, and a day later he removed the chin strap, re set the jaw and

*Nelson v Sandoli 209 N W 440

at that time the dentist under his direction wired the upper and lower teeth together. The week after the physician again manipulated the jaw after removing the wires, and again Dr. S replaced them under his direction. A few days later the patient dispensed with the services of Dr. W and went under the care of another physician.

The patient brought an action for malpractice against the dentist and the doctor as co-defendants, charging them jointly with negligence in: First, administering the anesthetic, second, extracting a tooth in addition to the impacted tooth, third, breaking the jawbone in extracting the impacted tooth, fourth, failing to properly set the fracture, and fifth, failing to properly take precautions against infection.

The case came on for trial, and the action was dismissed on a technicality as to the dentist Dr. S, leaving Dr. W in the position of being the sole defendant against whom a verdict might be rendered. Three expert witnesses, two of them physicians and one a dentist, took the stand on behalf of the plaintiff, and gave a great deal of testimony but the Trial Court ruled that they failed to give any proof to the effect that the defendant Dr. W was himself negligent, and directed a verdict in favor of the defendant, at the close of all the evidence, thereby also ruling that Dr. W was not responsible for the negligence of the dentist.

An appeal was taken on behalf of Miss N, and the important contentions made were first, that there was proof that Dr. W was negligent in administering the anesthetic and the aftercare, and second, that he was responsible for the negligence, apparently conceded, of Dr. S in permitting the jaw to break during the extraction.

The Appellate Court reviewed the testimony on the trial and found there was no evidence to warrant a finding that Dr. W, in administering the anesthesia or in caring for the plaintiff after the operation varied materially in his methods from methods approved and used by physicians and surgeons generally. Dr. W's liability, therefore, necessarily was dependent, if he was to be held liable in the case, upon the negligence of the dentist.

The Court in deciding that under the circumstances the physician was not responsible for the negligence charged against the dentist, said in part:

"We think this testimony has no tendency to show a joint employment of the

appellees to extract the tooth, or to establish any relation between them by virtue of which Dr. W would be liable for the alleged negligence of Dr. S. Dr. W did not undertake to extract appellant's tooth, or to have it extracted by Dr. S. There was no relation of partnership or agency between them. The most that the testimony tends to show is that Dr. W directed appellant to go to Dr. S for the purpose of having the tooth extracted, and that plaintiff employed Dr. S for that purpose and employed Dr. W to administer the anesthetic. Her statement that Dr. W consented to look after her interests in the operation is not susceptible of the construction that he thereby agreed to be responsible for Dr. S's negligence. At most he was to 'help' Dr. S.

"The mere recommendation by one doctor of another does not make the one liable for the malpractice of the other. This has been held to be true where one physician advises an operation, and, with the consent of the patient, arranges for it to be performed by another, a competent surgeon, whom he assists. And where the physician in charge of a patient calls a surgeon into the case to operate and assists in the operation by doing what he is directed by the surgeon to do, it has been held he is not liable for negligence in the operation, in the absence of negligence in recommending the surgeon, or on his own part in assisting him."

The Court further said:

"While the skill and knowledge required of a physician and of a dentist are the same in degree, they are obviously different in character. They must each possess and exercise the knowledge, skill and care ordinarily possessed and exercised by practitioners of their particular art in like localities, but the physician is not required to have or exercise the peculiar skill or knowledge required of the dentist, nor is the latter bound to possess the knowledge essential to the general practice of medicine or surgery.

"There is no testimony tending to show that Dr. W took any part in the actual extraction of appellant's teeth, except that he administered the anesthetic and assisted Dr. S by handing him instruments and disposing of blood cloths, by throwing them on the floor. There is testimony from one witness that at one time he suggested a change of forceps, but no showing that the suggestion was acted upon. * * *

"It is well settled that, generally speaking, a physician who merely administers an anesthetic to a patient who is operated on by another is not liable for the negligence of the operating surgeon."

The Court, therefore, we feel, very properly affirmed the judgment of the lower Court, there being no competent proof of his personal negligence, and he not being justly responsible for the negligent acts of the dentist, if in fact they were negligent.

Claimed Injury to Uvula

A child about four years of age was brought to the office of a doctor specializing in ear, nose and throat work for examination. The doctor found that the patient's tonsils and adenoids were enlarged and contained pus, and suggested their removal. The patient was, a few days later, brought into his office for operation, and he put the child under an ether anesthetic and performed an operation upon her for the removal of both her tonsils and adenoids. The operation was uneventful. The child was put to bed and about three hours later there was a slight oozing of blood from the child's nose. This was treated by dropping adrenalin into the nostrils and application of an iron sulphate solution. The hemorrhage stopped, and about six hours later the child was permitted to return to her home. The following day when the doctor attended her the patient was suffering from further bleeding and the doctor controlled the condition by injection. From that time the child's recovery was uneventful. The next the doctor heard of the case was when summons and complaint were served upon him commencing a malpractice action charging him with general negligence in the performance of the operation. It was ascertained that the claim which was being made on behalf of the child was that the doctor performing the operation had cut or amputated the uvula, as a result of which it was claimed the child had become anemic, unable to talk without stuttering and had suffered from hemorrhages. Physical examination was made of the child by a doctor on behalf of the defendant. The examination revealed that the child was in excellent health, having rosy cheeks and full red lips, with no indications of being anemic. Exam-

ination of the throat showed that the tonsils and adenoids had been removed with good results, that the child had only a rudimentary uvula, being no more than a curve in the soft palate, coming to a short point in the center of the soft palate. It was impossible for the doctor making the examination to find any indication that the uvula had been injured during the operation. The examining doctor also found that the child's voice was clear and distinct with no defects.

The case was apparently instituted in an attempt to obtain a settlement on a nuisance basis but of course no such settlement was made, and after the case had been pending for some time and no steps had been made by the plaintiff to bring it on for trial a motion to dismiss the case for lack of prosecution was made on behalf of the defendant doctor, which was granted, thereby finally disposing of the case.

Amputation of Leg Subsequent to Herniotomy

A general surgeon was consulted by a patient about sixty years of age who complained that he was suffering from hernia and stated that he desired to have an operation performed.

The doctor examined him and found that he was suffering from a condition of double inguinal hernia. The doctor explained to the patient that he would not advise an operation by reason of the age of the patient if it was possible to hold the hernia in place by means of a truss. However, the patient, in view of the possibility of strangulation, insisted that an operation be performed.

Patient entered a hospital and under a general anesthesia the surgeon undertook to perform the operation. The right side was first operated upon, which was uneventfully completed. He then undertook the operation on the left side, and during the completion of the operation on the left side hemorrhage developed, due to the fact that a blood vessel was located in an abnormal position. The bleeding vessel was tied off and the hemorrhage stopped. The patient went from the operating room in normal condition.

About five or six days later the patient complained of a coldness in his left leg.

Upon examination the left foot appeared to be pale. After several days elapsed the foot became discolored and painful. The condition became worse and two weeks after the operation the surgeon found it necessary to amputate the left leg through the middle third in order to prevent the spreading of a gangrenous condition through the patient's circulatory system which would in his opinion have been fatal. Thereafter the patient's recovery was good, and he left the hospital with an excellent result from the herniotomy.

A malpractice action was instituted against the doctor charging him with having performed the operation without taking the necessary precautions before the operation and in using improper and unsafe instruments. The claim was made that due to the negligence of the defendant a condition was permitted to develop which necessitated the amputation of plaintiff's left leg. An action was brought in a county considerably distant from where the defendant practices his profession and where the operation had been performed and a change of venue was obtained changing the place of trial to the county where the doctor practiced. Thereafter the case remained practically dormant for several years, and at the end of that time a consent to discontinue the action was obtained from the plaintiff's attorney.

Alleged Diathermy Burn

Plaintiff was employed as a night watchman. He claimed to have sustained a fall on some stairs about the premises where he worked, injuring his back. He reported the matter as a compensation case and was referred to a certain physician for treatment. The doctor called upon him at his home and found him in bed with a large mustard plaster on his back. The doctor removed the plaster and found that there was a burned condition of that portion of the back where the mustard plaster had been. He examined him and found certain minor abrasions which the patient claimed caused him a great deal of pain. The doctor prescribed sedatives for him. He saw him for a few days, at the end of which time he was able to return to work.

Shortly thereafter the doctor was again called to see the man and he was then complaining of a strained back. The doctor, upon examination, found a slight spasticity

of the muscles in the lumbar region. The doctor directed the application of hot packs and liniment rubs, and subsequently the patient came to the doctor's office for diathermy treatments which were administered at the suggestion of the Compensation Examiner. A number of mild diathermy treatments were administered from time to time, infra-red lamp treatments were also administered, as well as massage by means of an electric vibrator. Nothing out of the ordinary developed as a result of any of the treatments so long as he remained under the care of the doctor. The patient apparently was a malingerer attempting to magnify his complaints of pain in order to enlarge upon his claim for compensation.

Some time later patient started an action against the doctor which charged that the defendant had on one occasion applied a diathermy apparatus to him and had gone away to answer a call leaving the current turned on for a long time so as to severely burn him. Plaintiff claimed that as a result of the alleged burns he had five large permanent scars on his body. The doctor denied that any such burn ever developed or that he had ever left the plaintiff unattended during the administration of any treatment.

The case was brought on for trial before a court and jury and the issues of the case were submitted by the court to the jury, who rendered a verdict in favor of the defendant, thereby discrediting the story of the plaintiff and exonerating the defendant of all charges of malpractice.

A GRACEFUL TRIBUTE

Dr. Morley B. Lewis closed his retiring presidential address to the Suffolk County Medical Society on October 25 with these graceful verses:

"In the hustle and bustle of business,
With its slaving and saving and grind,
We're too apt to credit successes
To the works of our own hands and mind.

But I pause at this annual meeting
To give credit where credit is due,
To thankfully say that our progress results
From the friendship of such doctors as you."

Patient: "I understand fish is good for the brain. Can you recommend anything special?"

Doctor: "Well, you might begin with a whale."

NEBRASKA STATE MEDICAL JOURNAL.

Books

BOOKS RECEIVED

The Anaemias.—By Janet M. Vaughan. Octavo of 248 pages, illustrated. New York and London, Oxford University Press, 1934. Cloth, 12/6.

In this volume Janet Vaughan presents a timely exposition of the present knowledge concerning the subject. Based upon her own investigations and an intimate knowledge of the subject, she has successfully undertaken to simplify a state of confusion, almost chaos, existing in the literature.

Her classification is understandable, simple, and complete. She avoids as much as possible the use of new and doubtful terminology.

The various diseases (anaemias) are considered in a systematic and practical fashion—discussing synonyms, definition, geographical distribution, race, sex age, hereditary factors, symptoms, pathology, etiology, differential diagnosis and treatment. An excellent bibliography is included. The book can be highly recommended to all who come in contact with the anaemias, the practitioner as well as the expert hematologist.

MAX LEDERER

The Chances of Morbid Inheritance.—Edited by C. P. Blacker, M.D. Octavo of 449 pages. Baltimore, William Wood & Company, 1934. Cloth, \$5.00.

An authoritative and fairly comprehensive work permitted, and especially an opportune time.

reference to many diseases by a special writer, and it is difficult, in a work so constructed, to avoid slight repetitions.

Though a wide range of opinion exists as to many of the dogmas considered, the aim is to extract a fair average or estimate. For those who wish light on this subject this is an admirable work, perhaps easier for a mathematical than linguistic mind. It is a splendid effort to make useful knowledge available to physicians, even though many points are still hazy.

WILLIAM BROWNING

The Medicolegal Necropsy.—A Symposium held at the Twelfth Annual Convention of the American Society of Clinical Pathologists at Milwaukee, Wisconsin, June 9, 1933. Edited for the Society by Thomas B. Magath. Octavo of 167 pages, illustrated. Baltimore, Williams & Wilkins Company, 1934. Cloth, \$2.50.

This volume presents material by outstanding leaders in medicolegal experience. It is thoroughly reliable. It discusses the value of the medical examiner in contrast to the coroner's system. Details pointing a way for the further improvements to be expected in crime detection, in general the laws governing organs at necropsy.

It presents by a most experienced authority a detailed procedure in medicolegal necropsy. We must, however, caution that this work alone does not replace larger books which are necessary. Those interested in this subject should be familiar with this publication.

M. E. MARTEN

Mental Deficiency Nursing.—By O. P. Napier. Pearn 16mo of 281 pages. Baltimore, William Wood & Company, 1934. Cloth, \$2.00.

This is a unique compend written in an unusual style and stressing practical facts. The teaching and study methods are strikingly useful. It includes theoretic and practical branches of nursing study considerably beyond its specific scope. It is regrettable that the psychiatric group of disorders were not included, since much of the material is directly applicable to this field as well. The mental classifications, administrative features, and legal aspects are British. Instructors of student nurses in any subject should be given the opportunity of utilizing this small volume. The student nurse will certainly use it, and perhaps to the exclusion of larger texts.

IRVING M. DERBY

A Textbook of Authors. Edited Edition Octavo University Press,

The fourth true textbook presents its quality is appa of the infectious diseases are discussed by Lord Horder, who has been called "the first physician of England." The heart is covered by Price himself, the kidneys by

Langdon Brown and Geoffrey Evans, the digestive tract by Arthur I. Hurst, tropical diseases by Low and

is struck by the similarity can medicine. In spite students who have studied mis as though the common races so rapidly diffuses new knowledge that they remain more in intellectual balance than do aliens. At all events this book treats of medicine, in concept and procedures, much as our authorities approach it. It is up to date, and it is extraordinarily complete.

TASKER HOWARD

The Chemistry of the Hormones.—By Benjamin Harrow, Ph.D., and Carl P. Sherwin, M.D. Octavo of 227 pages. Baltimore, Williams & Wilkins Company, 1934. Cloth, \$2.50.

This book is written for the use of the laboratory worker who wishes to prepare active hormone fractions, or to isolate a chemically pure hormone. It is also useful to the student who wants a concise account dealing with the chemical characteristics of the hormones.

The authors must be commended on their bibliography and lucid presentation of their subject. Their bibliography, without attempting to be complete, covers most of the important contributions. Hence the book serves the needs of the laboratory worker not only as a reliable laboratory manual, but also as a useful source of references.

M. A. GOLDZIEHER

Parasitism and Disease.—By Theobald Smith. Octavo of 196 pages. Princeton, N. J., Princeton University Press, 1934. Cloth, \$2.00.

In this volume is found a comprehensive exposition of the groundwork and principles of the biological problem of parasitology in its broadest sense. Originally presented as the Vanuxem Lectures for lay students, the publication has been expanded to a text of instructive and highly interesting material, requiring more than superficial technical knowledge for proper comprehension. The major theme has been the historical development of understanding of the manifold subtleties existing in the balance between invasive diseases and their causative agents. This theme has been developed through phases of parasitic and cellular biology, immunology, epidemiology, and specific therapy. The mellow experience of the author is well reflected in his well rounded subject which will be stimulating for every reader.

IRVING M. DERBY

The International Medical Annual.—Year Book of Treatment and Practitioner's Index. 52nd Year, 1934. Edited by H. L. Lidy, M.D., and A. Rendle Short, M.D. Octavo of 579 pages, illustrated. Baltimore, William Wood & Company, 1934. Cloth \$6.00.

While medical literature is replete with novel suggestions, comparatively few seem worthy of outstanding merit. Most reports are merely repetitions and confirmations of accepted practices. For that reason, a skeptical comment by an editor, such as "copper is an unnecessary adjunct to iron therapy in the treatment of all forms of hypochromic anemia in human beings" may awaken those who fall into the rut of reaching out for everything that smacks of progress. There is some encouraging news regarding radiation for early cancer of the anus in preference to surgery. Also, there is a report on the successful removal of cataractous lenses with a fine electrocoagulating instrument known as an electrodiaphone. It is still new and therefore cannot be recommended for general use.

Whether we choose to agree or disagree with the many reports summarized in this annual, in either instance we should be satisfied. For when we agree, we are satisfied with existing knowledge, when we disagree, we find a stimulating basis to correct existing defects.

EMANUEL KRIMSKY

Industrial Toxicology.—By Alice Hamilton, M.D. 16mo of 352 pages. With subject index. New York, Harper & Brothers, 1934. Cloth, \$3.00.

This volume is one of a series of Medical Monographs. Dr. Hamilton well says that this vast subject can only be sketched briefly in the space allotted, but by

this very reason it is a valuable book for quick reference. The subject matter is replete with indices, to a bibliography of 655 items placed at the end of the volume; this is of great value to one interested in industrial medicine. Up-to-date information on recent studies in this field will be found. As a reference book it is worth while including in the library of the general practitioner.

A. E. SHIPLEY

That Heart of Yours.—By S. Calvin Smith, M.D. Octavo of 212 pages, illustrated. Philadelphia, J. B. Lippincott Company, 1934. Cloth, \$2.00.

So much vague information concerning the heart and heart disease is prevalent among the laity, that the author has presented accurately much knowledge and information concerning this organ and its diseases in language which will tend to allay fears in one who believes that his heart is at fault. It is surprising how much the author has been able to include in this volume; the anatomy and physiology of the normal heart, explanation of valvular lesions, musculature failure and methods of conserving the action of a heart that is under normal. This work has information for the physician as well as for one who has not studied medicine.

HENRY M. MOSES

Child Guidance Clinics.—By George S. Stevenson, M.D. and Geddes Smith. Octavo of 186 pages. New York, The Commonwealth Fund, 1934. Cloth, \$1.50.

This book is a record of the origin and growth during the past 25 years of the child hygiene movement in the United States. It gives a detailed account of the establishment of the clinics in various parts of the country, of the aims of the clinics to acquaint the local communities with the nature of maladjustment in children and the best means to combat them. Those who devote themselves to psychiatric problems as they affect children, will appreciate the enormous tasks that faced the pioneers in this work. The cooperation of the parents, of the teacher, and others in authority are needed to achieve practical results with prepsychotic and maladjusted children. This book is recommended to all interested in mental hygiene work.

JOSEPH SMITH

The Social Adjustment of the Tuberculous.—By Beulah W. Burhoe. Octavo of 55 pages. New York, National Tuberculosis Association [c. 1934]. Paper, 50¢.

This book is a brief summary of the various schemes attempted in our country toward rehabilitating the "arrested" tuberculous patient and fitting him for future economic independence. A realization that no one plan has yet been developed that will fully cover this group of physically handicapped, dawns upon the reader, as does the fact that every scheme yet devised is economically unsound and dependent upon charity. It is a well compiled review of this special problem.

CHARLES E. HAMILTON

Handbook of Therapeutics.—By David Campbell, M.D. Second Edition. 12mo. of 444 pages. Baltimore, William Wood & Company, 1934. Cloth, \$4.75.

The revised edition of this book has been brought up to date by numerous additions. It is a good handbook, and the author is very economical of words, but of its four hundred odd pages, about a quarter are devoted to general considerations and the remainder cover the treatment of diseases usually classed as medical, including the subheads of neurology and endocrinology. It is a question whether the amount of information which could possibly be crowded into this space could be worth the amount asked for the book, except to a student who must be able to satisfy an examiner with one type of treatment for each disease. As a guide to treatment it is a bit thin.

TASKER HOWARD

Collected Papers of the Mayo Clinic and the Mayo Foundation.—Edited by Mrs. Maud H. Mellish-Wilson and Richard M. Hewitt, M.D. Vol. 25, 1933. Octavo of 1230 pages, illustrated. Philadelphia, W.B. Saunders Company, 1934.

The volume of the Collected Papers for the year 1933 brings together a most interesting assembling of material in the various branches of medicine, covering all phases. The presentation, in short form, appeals to one in looking over the book. Because of the wealth of clinical material and the thoroughness of the study, the conclusion adds to the wealth of medical literature. The volume is valuable for short reading at odd moments. Those who have had occasion to read previous copies can appreciate the opportunity afforded in the perusal of present issue.

E. W. SKELTON

A Short History of Some Common Diseases.—By Divers Authors. Edited by W. R. Bett. Octavo of 211 pages. New York and London, Oxford University Press, 1934. Cloth, \$3.50.

It is to be hoped that the briefness of these short accounts by distinguished English authors will tempt many readers who would perhaps side-step a more solid presentation. There is considerable variety in style; scholarly, sketchy, with adequate bibliography, or none at all, but all well written and interesting to the medical reader and no doubt to some laymen. That the book lacks ponderosity may be gathered from the editor's engaging inscription, "To my illusions which have in perpetuity enriched my life."

TASKER HOWARD

A Compend of Diseases of the Skin.—By Jay F. Schamberg, M.D., and Carroll S. Wright, M.D. Ninth Edition. 12mo. of 331 pages, illustrated. Philadelphia, P. Blakiston's Son & Co. [c. 1934]. Cloth, \$2.00.

This ninth edition of Schamberg's compend of skin diseases has some changes in the text, bringing it up to date; and a few of the photographic reproductions have been replaced by better ones.

The book fulfills its purpose very well by giving sketchy outlines of most of the skin diseases, which will serve one to make a differential diagnosis preliminary to closer study in a more comprehensive text. It will also serve the medical student well in grasping the essentials of the fundamentals of dermatology and the various cutaneous disorders. The tables of differential diagnosis are good and the outlines of treatment helpful.

E. ALMORE GAUVAIN

Practical Medicine Series.—Comprising Ten Volumes on the Year's Progress in Medicine and Surgery. Series 1933, Chicago, The Year Book Publishers [c. 1933]. The 1933 Year Book of General Therapeutics. Edited by Bernard Fantus, M.D. 12mo. of 464 pages, illustrated. Cloth, \$2.25.

In roaming through a book on therapeutics with its generous and diverse remedies, one wonders why there is such a liberal acceptance of substances supported by unfounded and extravagant claims. A critical evaluation reflecting a conservative attitude should therefore be welcomed. In the treatment of urinary infections, antisepsics have proved disappointing according to one author who is convinced that "water is still the physician's best friend."

There are still some physicians who cannot think of parting with old tuberculin, in spite of the fact that definite proof as to its efficacy is lacking. Maybe it's the thought of the "old reliable" that keeps them so attached to this agent.

That insulin therapy may cure diabetes is the contention of one author who reports twenty cases.

One author tells us what we have always known, i.e., that salicylates do not prevent rheumatic relapses.

Other than being a resumé of articles, this number of the Practical Medicine Series is devoid of stimulating interest. The editorial comments are few and far between, and there are very few contradictions to the claims for these various substances.

EMANUEL KRIMSKY

Essays on Chronic and Familial Syphilis.—By Griffith Evans. Octavo of 91 pages, illustrated. Baltimore, William Wood & Company, 1934. Cloth, \$3.00.

This is a very interesting little book and will be read, I think, with equal interest by the syphilographer and the general practitioner.

The author takes the position that "chronic syphilis" and hereditary or familial syphilis may be diagnosed, if one is on the lookout for it, far more commonly than is ordinarily supposed. The Wassermann reaction is entirely negative in more than half of these cases. The diagnosis must be made on other physical signs and by exclusion. Many vague symptoms which have resisted all other forms of treatment, respond promptly to a short course of specific therapy. Whether one agrees with the author or not, it is a strikingly interesting book and well worth the time spent in reading it.

N. P. RATHBUN

Midwifery for Nurses.—By Henry R. Andrews, M.D., and Victor Lack, M.B. Seventh Edition. 12mo. of 268 pages, illustrated. Baltimore, William Wood & Company, 1934. Cloth, \$2.50.

When a book has reached the seventh edition, and has been translated into three foreign languages, it must have considerable merit.

In this new edition, Dr. Lack has followed Dr. Andrews plan and has kept the volume brief and simple. From its study, however, a nurse may learn all that it is necessary for her to know about pregnancy, labor, puerperium, and infant care.

The authors are to be congratulated on the simplicity with which they tell a very complete set of facts.

WILLIAM SIDNEY SMITH

**THE TREATMENT OF CHRONIC INTRACTABLE HEART DISEASE
BY TOTAL THYROIDECTOMY**

DAVID D. BERLIN, M.D., and HERRMAN L. BLUMGART, M.D.

From the Medical and Surgical Services and the Medical Research Laboratories of the Beth Israel Hospital, the Department of Medicine, Harvard University Medical School, and the Department of Surgery, Tufts College Medical School, Boston

Surgical intervention is undertaken for various purposes. One group of operations has as its objective the extirpation of abnormal structures, such as malignant tumors. Another group of surgical operations attempts to attain restitution of normal anatomic structure; the treatment of fractures falls in this category. A third group of operations has as its objective the restitution of certain normal physiological relationships. The treatment of chronic heart disease by complete removal of the thyroid gland is representative of this latter group. In patients with intractable congestive heart failure, the blood supply is inadequate for the metabolic demands of the tissues. In angina pectoris, the available coronary blood supply is not sufficient for the needs of the heart. By lowering the metabolic rate by total thyroidectomy, the discrepancy between tissue needs and blood supply is abolished and these two important fundamental factors are brought into proper relationship. Many aspects of the problem of treating patients with chronic heart disease by complete removal of the normal thyroid gland have been presented in other communications.^{3-6,10,11} It may be well at this time to present an abstract of some of these problems with particular reference to the surgical considerations.

In two patients with congestive heart failure who were operated on in October and November, 1932, a minute residue of thyroid tissue was left at the upper pole or deep in the esophageal sulcus.³ In both

instances, clinical improvement, paralleling a drop in the metabolic rate, was only temporary. This experience as well as that of other previous investigators indicated that nothing short of complete removal of every vestige of thyroid tissue would consistently accomplish persistent lowering of the metabolic rate. The use of x-ray, either as an adjunct to such maximal subtotal thyroidectomy, or employed alone, failed to be of any value.³

SELECTION OF CASES

The operation at the present time should be undertaken only in such patients who in spite of every available treatment have failed to maintain improvement and are incapacitated. Patients with angina pectoris are by far the better operative risks, for they usually show no evidence of decompensation; patients with status anginosus or angina pectoris complicated by attacks of cardiac asthma are more serious risks. Patients with congestive failure, however, must be selected with great care. Removal of the thyroid gland presumably does not alter the underlying cardiovascular pathology. If the underlying pathological process is rapidly progressive, it will probably continue to be so after operation, and the patient will obtain improvement over only a relatively short period of time. Patients who give a history of short rapidly progressive disease are therefore unfavorable subjects. In this category are included patients with malignant hypertension, patients with short rapidly pro-

gressive histories of congestive failure due to arteriosclerotic, hypertensive, or rheumatic heart disease. Patients with syphilitic cardiovascular disease similarly are unfavorable subjects. The operation should not be undertaken in the presence of active pulmonary infection, or in the presence of clinical evidence of active rheumatic infection. Patients with impaired renal function and nitrogen retention are poor operative risks. Before operation, it is of the greatest importance to keep patients at complete bed rest until the signs of congestive failure disappear, so that operative complications will be minimized. Most of our postoperative deaths have been in patients who, in spite of long preoperative care, have nevertheless shown evidence of congestive failure as indicated by râles at the bases of lungs, enlarged liver, and signs of peripheral edema. Operation should be undertaken only after the patient's condition has been improved to the fullest possible extent.

Experience has shown that a basal metabolic rate of less than minus 15 per cent prior to operation is an unfavorable factor and that the operative procedure is contra-indicated when the metabolism is below minus 20 per cent. Success after total thyroidectomy predicates the presence of at least some reserve on the part of the weakened heart. The patient who preoperatively shows no evidence of such cardiac reserve, as manifested by failure to show improvement with complete bed rest and digitalis, is a poor operative risk and will probably not be greatly benefited by the operation. An ideal subject for this procedure is one who loses all signs of congestive failure on rest in bed, but regularly shows evidence of decompensation when he deviates from this régime. The patient has a basal metabolic rate above minus 10 per cent. In such a patient, a lowered metabolic rate may result in striking clinical improvement, with the capacity for reasonable activity and usefulness without return of failure.

ANESTHESIA

Earlier in this work gas-oxygen anesthesia, with adequate preliminary sedation, was employed. The use of local anesthesia in a few of the patients with severe hypertensive heart disease with congestive failure proved so satisfactory that it has since been generally adopted. The results in the

last 22 patients thus operated upon have been so satisfactory that we unhesitatingly recommend it as the anesthesia of choice in practically all cases.

OPERATIVE TECHNIC

Compared with the subtotal resection of a hyperplastic gland, total ablation of the normal thyroid is less troublesome, for bleeding is a less serious problem. The friability of the diseased hyperplastic gland often provides considerable technical difficulty which is not encountered in the removal of the normal gland. In total thyroidectomy, however, it becomes necessary to expose the recurrent laryngeal nerves and the parathyroids to great danger of injury in the process of removing every vestige of thyroid tissue.² While injury to one nerve is not attended by serious consequences, bilateral nerve paralysis is calamitous and the danger of its occurrence must be always regarded as imminent. To obviate this disastrous complication, direct laryngoscopic examination of the vocal cords is always made after the removal of the first lobe of the thyroid.⁷ If there is evidence of one-sided nerve injury, the operation is terminated at this point and completed at a future date if the cord regains its function. Direct laryngoscopic examination should be adopted in cases operated upon under local, as well as in those operated upon under general anesthesia, since no apparent change in the quality of the spoken voice may occur after unilateral nerve damage. Reliance on the changes in the quality of the voice may lead to disastrous consequences.

RECURRENT LARYNGEAL NERVES.—Bilateral recurrent nerve paralysis has not occurred in this group of patients. There were 7 temporary one-sided vocal cord paralyses, possibly due to inadvertent pinching of the nerve during operation. There were 3 permanent unilateral cord paralyses; one followed accidental severance of the nerve, and another proved at postmortem to have resulted from ligation.

Appreciating that an accurate knowledge of the course, position, and possible variations of the recurrent laryngeal nerves are of great importance to the operator, careful studies of this nerve were made in the dissecting room during the past 2 years.² Detailed dissections of 140 nerves in 70 cadavers disclosed that 10 per cent par-

trially penetrated the gland, and 25 per cent coursed through the adherent zone. The latter region represents the area of fixation of either lobe of the thyroid to the trachea just below the anterolateral aspect of the bar of the cricoid cartilage at the level of the first and second tracheal rings. In this region the nerve may be concealed beneath a curtain of fibrofascial tissue. If one is to reduce the incidence of nerve damage, both of these 2 positions of the nerves must be constantly borne in mind. To identify and preserve them intact, it is necessary to explore the gland substance in its deep posteromedial aspect and the adherent zone by means of careful blunt dissection. Fortunately, the majority of the recurrent laryngeal nerves (65 per cent) are found coursing safely in the tracheo esophageal sulcus, in which position the nerve is best protected against serious operative injury.

In approximately 35 per cent of the patients operated upon, a pyramidal lobe was found. Since this structure is capable of sustaining the metabolic level, careful search should be made for it during operation and, if found, traced to its uppermost limit and removed. The fixation of the gland may be so marked and the gland substance extend so deeply in the groove between the trachea and the esophagus that the operator may be tempted to leave a remnant of thyroid tissue in this area because of fear of injury to the nerve. This fragment, however, must be extirpated for it may be sufficiently liberal in size to preclude the development of a permanent lowering in the basal metabolic rate, without which lowering a successful therapeutic effect is not to be anticipated.

THE PARATHYROID—These small, yellowish brown, finely granular, flattened, pea sized glands which receive their blood supply from a slender arterial twig usually arising from one of the terminal branches of the inferior thyroid artery, are most commonly located near the level of the lower poles of the thyroid gland. At operation, approximately 66 per cent of the parathyroids were identified in this area, 22 per cent were found on the posteromedial aspect near the junction of the middle and upper thirds of either lobe, and the remaining 12 per cent scattered in atypical locations. It has been noted that parathyroid bodies may be found in the

superior mediastinum, beneath the trachea or esophagus, on the anterior aspect of the thyroid gland, or embedded within the split layers of the true capsule of the gland.

One hundred and sixteen parathyroid glandules were identified and preserved at operation in this group of 60 patients. In only one patient none was identified at operation, and no signs or symptoms of tetany developed postoperatively. It is now felt that deliberate search for the parathyroids is not especially indicated, because it may result in at least a temporary interference of their function by disrupting their lymphatic blood or nerve supply. On the other hand it is essential to possess an accurate knowledge of their appearance and be able to distinguish them from neighboring lobules of fat and islands of aberrant thyroid tissue, lest they be sacrificed unnecessarily. When identified embedded in the thyroid gland or enclosed within the split layers of the tunica propria they should be dissected out and reimplanted in the sternomastoid muscle, they should be similarly reimplanted if they are accidentally removed during operation.

A routine examination of each patient for clinical signs of developing tetany is made at frequent intervals each day during the first postoperative week. At the time of each examination the patient is directly questioned concerning the presence of sensations of numbness or tingling. If signs or symptoms of tetany are elicited, calcium chloride solution (8 c c of 35 per cent solution every 3 hours) is administered orally. If signs or symptoms persist, calcium medication is increased, calcium chloride solution intravenously (10 to 20 c c of 10 per cent) may be indicated occasionally. Medication is gradually reduced, and omitted when the signs of parathyroid insufficiency remain absent.

In the first 60 cases operated upon, 10 patients developed some of the signs or symptoms of parathyroid insufficiency. No case with spontaneous carpopedal spasm or convulsions was encountered. In 9 of these 10 patients, parathyroid insufficiency was transient, all clinical signs and symptoms disappearing within the first 2 postoperative weeks. One patient, now 9 months postoperative still requires calcium medication to control mild symptoms of hypoparathyroidism.

POSTOPERATIVE CARE

The postoperative treatment of our patients demands the same careful supervision that all patients with heart disease require. In addition, the level of metabolism in each patient must be carefully regulated.⁵ By the administration of small doses of thyroid daily, practically all patients can be maintained at a metabolic level of minus 25 to minus 30 per cent, at which level the untoward signs and symptoms are controlled.^{6,9} Without thyroid medication, we have found that practically all patients will eventually develop myxedema, with weakness of the legs, emotional irritability and mental slowing. This metabolic level, while freeing patients from the untoward signs and symptoms of myxedema, nevertheless requires less work on the part of the heart and releases this organ from much of its previous burden.

RESULTS

Of 40 patients that were operated upon for congestive heart failure, 22 have maintained their compensation 2 to 17 months after operation; 5 had temporary recurrent decompensation and at present are well and active; 6 died at one to 11 months subsequent to operation; 2 showed no improvement; and 5 are too recently postoperative to evaluate the extent of the clinical improvement. All of the 22 patients who have maintained compensation are either working or able to work.

A survey of the results in 20 patients with angina pectoris shows that there was marked improvement in 13 patients who have now gone 2 to 17 months postoperatively. They have had no anginal attacks and have required no nitroglycerin. In 4 patients there was moderate improvement; in 3, little or no improvement. There were no operative or subsequent deaths in this group.

In a series of 60 patients, 6 operative deaths have occurred. All of the deaths occurred during the period of our earlier experience in patients with advanced congestive heart failure. On the basis of our present criteria for the selection of patients for operation, 4 of these patients undoubtedly would be denied this therapeutic measure, because their congestive failure was so severe that only moderate improvement was evident after prolonged bed rest and diuresis. Cardiac failure and bronchopneumonia, as disclosed by autopsy, was the

cause of death in all 6 cases. The last 22 consecutive patients have been operated without mortality.

DISCUSSION

DR. WILLIAM BARCLAY PARSONS, *New York City*: I was glad to hear the author stress the need of the greatest care in, first, the selection of cases, secondly, their study and preparation, and thirdly, the important points in the operation itself. It must constantly be kept in mind that the production of a profound hypothyroidism is not to be undertaken lightly, that there are definite handicaps associated with it, and that it is expensive to control it with organotherapy. However, it is a price that may be worth the paying for liberation in one group of cases from bed-fastness and in the other from unbearable or crippling pain. If the individual has become completely dependent on other people, economically, physically, and spiritually, any easing of his situation is a real boon, not only to him but also to his family.

We have only a small series to report at this time, merely 6 cases with no operative deaths. One case unfortunately developed lobar pneu-

monia on the 28th day postoperatively from which he succumbed. However, he had been up and about, and even walking out of doors, so he need hardly be counted as an operative fatality. Although the series is small, we do feel that we have one important point to offer in the preparation and care of these cases, namely, the use of oxygen. Dr. Alvan L. Barach, of the Presbyterian Hospital in New York, who suggested this procedure, will discuss the subject at greater length but has kindly permitted me to quote him. He conceived the idea of carrying these patients in the oxygen chamber because of his experience with oxygen therapy in heart disease, having used it to control severe decompensation. On theoretical grounds this is in harmony with the findings of Blumgart and his co-workers insofar as the heart load is concerned in reference to blood flow. By raising the arterial blood oxygen the diminished blood flow rate becomes adequate to supply the tissues with oxygen. Barach observed diminution in edema and cyanosis, increase in vital capacity and restoration of compensation. Many of his cases decompensated again after removal from the oxygen room, showing that this method was merely of temporary benefit, but that it might be of real use in preparation for a procedure designed to lower the heart load.

He therefore suggested that the patients who after study were scheduled for total thyroidectomy be placed in the oxygen chamber at a concentration of 50 per cent, that they be operated on receiving oxygen by nasal catheter, and then returned to the oxygen room for several days after operation. The rationale of this course is as follows. First, the preoperative treatment of the cardiac with oxygen produces in a large number of cases a state of compensation, even in patients who have failed to respond to other treatment. Operations on patients who are decompensated are attended with a very high mortality rate. Secondly, the inhalation of oxygen during the operation decreases strain on a damaged heart. Since the normal heart has a slower heart rate in an oxygen enriched atmosphere and since the damaged heart shows an improvement when it is experiencing difficulty in meeting the demand for an adequate blood flow when oxygen is administered, it seemed a physiologically rational procedure to mitigate the strain incident to an operative procedure by supporting the cardiac muscle at the time of operation. The cardiac muscle is especially sensitive to lack of oxygen, and to provision of an increased oxygen supply. Thirdly, the inhalation of oxygen after operation seemed indicated to sustain a heart already near to insufficiency by decreasing the effort made upon it. The essential load the heart has to assume is the provision of oxygen to the tissues by maintaining an adequate blood flow. If an increased supply of oxygen is afforded by increasing the amount of oxygen in the arterial blood through the inhalation of an atmosphere two and a half times that ordinarily present in air, the heart is able to contract both less frequently and more efficiently in the performance of the additional work incident to the operation.

The preoperative, operative, and postoperative treatment with oxygen of the patient with heart disease who is subjected to an operation appears justifiable because it fosters in the cardiac muscle an improved tone or function, before operation during it and after operation. The physiological

response of the normal and the damaged heart to a provision of an increased oxygen supply is the foundation of the procedure. Undoubtedly, many cardiac patients will weather the storm without oxygen, but the fact that a greater mortality has been demonstrated in patients with heart disease, even in the stage of compensation, both in routine operations as well as thyroidectomy, is justification for minimizing the procedure's hazard with a remedy that is known to support cardiac function. Once cardiac failure has begun, following operation, it is more difficult to alter the downward course than it is to prevent it.

The results have proved distinctly satisfactory. One patient with auricular fibrillation showed a rise in the apical pulse on the day of operation up to 100, but the others have failed to show even this slight reaction.

We have refused operation on one patient who failed to show satisfactory improvement under oxygen. In addition to advanced, though apparently stationary cardiac decompensation he also had severe renal disease. After a few weeks in the oxygen room he still had his edema, and his blood showed rising nonprotein nitrogen values. As he fell into one of the classes already mentioned by Dr. Blumgart as having a poor prognosis operation was withheld for the reason that we feel that it is of real importance to employ surgery only when there is a reasonable basis for assuming some cardiac reserve. Until more data on the results of this procedure are available we should be most conservative in extending the field of operability.

I was glad to hear Dr. Berlin state that he is using local anesthesia. It is certainly adequate, the patients for the most part have attained a definite detached objective point of view far removed from that of the hyperthyroid or ordinary thyroid patient, and require all the oxygen they can possibly obtain. If the theories upon which this whole procedure is based have merit, then any type of inhalation anesthesia is contra-indicated, as no step should be omitted which may contribute to the factors of safety. Dr. Berlin has pointed out the necessity of the utmost care in respect to the parathyroids and the recurrent nerves, and the difficulties in the zone where the lateral lobes are adherent to the trachea. These points are thoroughly well taken and deserve strict attention. I have found that in total, as well as in subtotal thyroidectomy division of the isthmus is a step that simplifies the difficult part of the operation. After liberation of the superior pole, if the isthmus is divided the lobe may be raised and easy access obtained medially and laterally to the area occupied by the parathyroids, to the course of the nerve and that trying area where the gland is adherent to the trachea. As these glands are small and pliable, though not friable, it is then a relatively simple matter to attend to the vessels running from parathyroids into thyroid, or to dissect out an embedded parathyroid, as one can see both sides of each structure.

Our results are of too short a period to warrant reporting except to state that the three cases of chronic decompensation, all women, have been liberated from bed, and one angina case of over two months standing has been relieved of pain. We have not as yet stabilized them on their dosage of thyroid extract.

MAN AS A COMPLETE ORGANISM—IN HEALTH AND DISEASE

GEORGE DRAPER, M.D.

From the Department of Medicine of Columbia University, College of Physicians and Surgeons, and the Presbyterian Hospital, New York City

When a new patient enters the consulting room there is an instant, measured by the twinkling of an eye, in which the physician receives a sharp impact from the approaching personality. At that moment it is not a question of "what ails the man" but rather "what manner of man is here." By the time the patient has crossed the room, we have observed his size, general shape or outline, facial design and expression, posture, gestures and gait, and "personal aura" which is perhaps a composite of his natural temperament and the momentary state of his emotional tension. This first and invaluable impression is formed in the field of perceptive or intuitive knowledge. In most cases all our subsequent investigations serve to confirm the swift, original perception. But there are enough misleading judgments of this sort to enforce a thorough study of the total personality of every patient. This, I believe, is just as necessary a part of the physician's task as examining the evidence of pathological processes.

Until the advent of laboratory methods, our predecessors in medicine drew freely upon their knowledge of the man to help them in the management of the patient. The great doctors of the past were not afraid to rely upon perceptive knowledge. But in a curious way much of this courageous reliance upon one of our most valuable endowments has dwindled under what is perhaps a false interpretation of science. But before proceeding further to develop the main theme of this essay, a brief inspection of two basic systems of thought is essential to its purpose. The first is concerned with the two types of knowledge, to one of which reference has just been made. Schopenhauer¹ has discussed them fully under the names "perceptive knowledge" and "abstract knowledge." The former expresses a deeprooted biological asset which is not subject to reason or cultivation; the other is a measured quality, teachable and purely rational. The growth of all understanding of life has depended upon the interaction of both sorts of knowledge.

Notwithstanding, however, the firm reliance which Man, in company with other animals, has justifiably placed in the perceptive type of knowledge, he continues to seek for a kind of certainty which, rightly or wrongly, he believes can be more surely found in reason. So far as natural phenomena outside himself are concerned, one can readily understand his attitude. The obvious yet unexplained menaces to life and well-being which he has met and still will meet in his environment, lose much of their terror for him when they are rationally explained; furthermore, many of them have been rendered innocuous through the practical application of abstract knowledge. But the important factor in his environment, which cannot be fully dealt with by the exercise of reason alone, is his fellow man. One does not have to seek far for an explanation of this serious failure or limitation to the force of Reason. It is to be found in that irrational other side of himself, that submerged portion of his own mind, where feeling and emotion reside, where perceptions are received, and whence imagination takes flight. And yet even the phrase "that irrational other side of himself" connotes a division of that very wholeness which it is our purpose to consider.

In the progress of civilization, the demand for certainty continually increases. Furthermore, it has become stronger in proportion to the success with which, in the sense of abstract knowledge, the Unknown has been converted into the Known. The fodder for the certainty appetite has been supplied by Reason. Consequently the reasoning faculty, and its accepted expression—Science—has become the shibboleth of modern times. It follows from that, that Man, striving continually to turn Imponderables into Ponderables, and often successfully achieving the result, becomes increasingly unwilling to admit the existence of the former. He therefore grows more and more skeptical of perceptive knowledge, or empiricism.

Clearly there is a strange lack of logic in this trend of Man's thought; for, whether

he will or not, the subcerebral machinery of the sympathetic nervous system, endocrine glands, and nonstriated muscles, lying at the psycho-physiologic border, will always move swiftly to solve a vital problem before rational thought process can begin to formulate an explanation or direct a course of action. On the other hand, the ultimate solution of difficulties such as epidemic disease or poisoning by the venom of serpents, rests upon knowledge of the

relationship between a subconscious fear and peptic ulcer. Yet for many years doctors have been aware that there was a connection between what they have called "worry" and that particular malady. Furthermore, it is common experience that diets and careful attention to acid-base balance will not surely cure the ulcer. From the illustrations just given it is apparent that situations may arise in the course of life which call for either one or

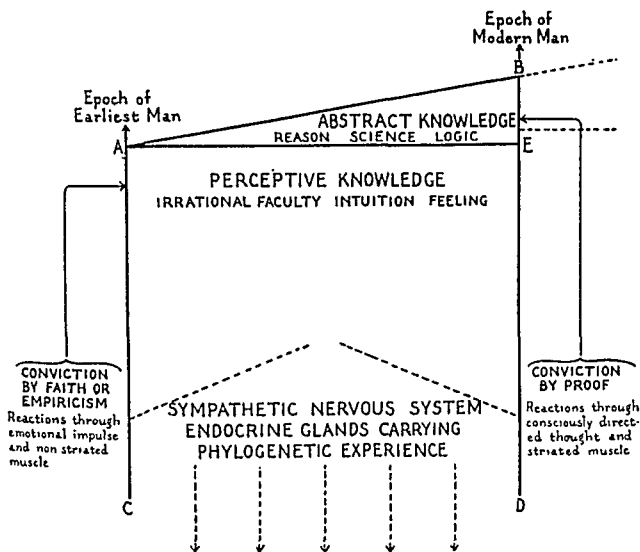

Fig. 1.—Diagram showing the structure of the Knowledge Bud.

abstract type, which satisfies Reason and is applied by it. Primitive man well knew the menace carried by these forces of nature, but his perceptive knowledge of them did not suffice to give him security. The magic processes devised by his imagination to combat them were inadequate. Even the "gods" failed him there. Yet in dealing with those diseases which arise from physiological faults flowing in turn from emotional maladjustment, Science is scarcely in better case. There is no mechanism of rational thought which can express in mathematical terms the causal

the other, or both kinds of knowledge—"perceptive knowledge" and "abstract knowledge."

Perhaps a diagram may help to clarify the notion of the two, which together make up the whole knowledge content: (Fig. 1.)

The irregular trapezoid A, B, C, D, represents the complete mind. The quadrilateral area, A, C, D, E, represents the unreasoning portion. Its lower side is left open to indicate that its content extends infinitely deep in the phylogeny of man. The triangle, A, B, E, represents the rational part of the mind and its shape

implies a gradual growth from the time of the earliest human beings.²

The second system of thinking involves two different attitudes in biology. One, known as *elementalist*, attempts to explain the organism by an analysis of its parts; the other, known as *organismal*, holds that the organism is greater than its parts and determines their nature. Thus these opposing schools of biological thought provide two avenues of approach to the study of any living organism—Man, let us say.

The *elementalist* starts by taking him to pieces structurally and functionally. Anatomists have shown that he has a skeleton, muscles of two sorts, internal organs, and a nervous system with two divisions, and objects called endocrine glands. Physiologists have demonstrated the function of many of these parts. Histologists have reduced man to smaller pieces, called cells. Finally, the bio-chemists and physicists have split him into those lesser units, atoms and electrons. Furthermore, psychologists have dissected his mind and emotions. Indeed, we can truly say from this point of view, that we know all about Man.

The difficulty, however, with this sort of knowledge of human beings, is that the skeleton, the muscles, or the organs are only those and quite useless until each and all combine and function smoothly together in the service of some particular person. From this standpoint, it will be seen that there is no resemblance in kind between the human heart or stomach, let us say, and the whole man. But there is a clear resemblance in kind between the heart muscle cell, or the peptic cell, and the whole man. This resemblance is due to the fact that each is a complete organism, each has a structural organization, functions purposefully, and subordinates to its needs the elements of which it is composed. The human heart and stomach, on the other hand, obviously can function only as integral and subservient parts of the individual human being. The notion is expressed in slightly different terms by stating that no two stomachs or intestines, and no two hearts react similarly to any ingested food or poison or emotion. This is true because the heart or gastro-intestinal tract are but representative segments; actually the whole person is the circulatory or digestive mechanism. And as the whole man responds to the pressure of the whole environment, so will any of his parts

respond—for each cell and system within him is stamped indelibly with his special mark. This has been called the *personality*.³ The biological basis for this conception is doubtless to be found in the gene which will be further discussed in another article.

Thus it becomes evident that even the most painstaking studies of its elements do not fully enable us to comprehend that living whole which never ceases to display its distinguishing particularity. The school of biological thought known as *elementalist* undoubtedly provides the physician with a much needed knowledge of the parts of our complex machine. But it leaves us like children who have taken a watch apart—helpless and dismayed among the mass of tiny pieces, meaningless and useless in themselves. The expert watchmaker, however, not only possesses a knowledge of the parts, but knows how they should stand and function in relation to one another. He knows the connection, and integrations of cogwheels, and springs, and jewels; finally in the special make of the watch he recognizes the unique organism to which all of the parts are subordinate.

Nicola Pende, in Genoa, has epitomized the point in the aphorism printed over his lecture hall: "Anatomy and Physiology separate the organism—The Clinic reunites them." The organismal point of view in biology has been most ably presented by W. E. Ritter⁴ and by E. S. Russell.⁵ At the outset of his book (p. 27) Ritter says: "If my basal proposition be true, that the organism taken alive and whole is as essential to an explanation of its elements as they are to an explanation of the organism, then it would follow that all attempts to assign explanatory values to the elements in their relation to the whole organism, while at the same time denying either expressly or tacitly, similar values to the entire organism in its relation to the elements, must fail in large degree."

In discussing the same subject, Russell says of Aristotle: "He gave creative function the priority over structure; he held that the whole was greater than its parts." (p. 17). And again in Russell's own definition of organism. . . . "The actions of the whole have a unique character, which renders them irreducible to processes of lower order." (Page 172.)

In further support of the importance of the organismal point of view, we may quote from Whitehead⁶: "If we wish to throw

light upon the facts relating to organisms, we must study either the individual molecules and electrons, or the individual living beings. In between we find comparative confusion." A similar thought is expressed by E. B. Wilson¹ in discussing multicellular organisms: "The real unity is that of the entire organism and as long as its cells remain in continuity they are to be regarded, not as morphological individuals, but as specialized centres of action into which the living body resolves itself, and by means of which the physiological division of labor is accomplished." The notion of specialized centres of action advanced by Wilson as an interpretation of the cell is reflected in the discoveries of Vogt, Spemann and of Coghill. Vogt⁸ shows by means of appropriately applied dye stuffs that early amphibian embryos are composed of a mosaic of discrete cell masses, and that each one of these cell blocks goes on to the formation of a specific adult part or system. The predestination of each block apparently is constant so that the presumption seems justified that this segment of the embryo will develop, for example into liver, that into heart, and another into central nervous system. Spemann⁹ then found that if presumptive abdominal skin from one gastrula were transplanted into the region of the future medullary plate of another, the transplanted skin developed into some part of the central nervous system. It is as though the gastrula receiving the transplant forced the alien cells into subservience and conformity with its needs as a complete organism. Further discoveries of Spemann, especially in connection with his "organizer" principle will be discussed in a subsequent essay. Still more impressive support for the organismal point of view is found in Coghill's¹⁰ studies of the behavior of *Amblystoma* embryos. He traces the development of body movements from the non motile to the adult stage in relation to the growth of the central nervous system. At one point in his argument the following passage occurs: "In like manner, the tissues of the tongue receive branches from motor neurones that are engaged in integrating the trunk long before the tongue has muscle tissue in it. It is therefore the potentiality of the functional neurone to grow in embryonic fashion that gives to the organism as a whole its ability to subjugate new parts and thereby maintain its

unity during the development of behaviour. Such growth of the already conducting neurones accomplishes then, the primary function of the nervous system: the maintenance of the integrity of the individual while the behaviour pattern expands."

An interesting illustration of this principle of organismal unity drawn from the field of pathology, is seen in the recent observations of O. H. Robertson¹¹ on the behaviour of pulmonary alveolar epithelium during pneumonia. These cells, in health perform the highly specialized function of aiding in the exchange of gasses between air and blood. During pneumonia Robertson observed that they take on a vigorous phagocytic action and are largely occupied in the successful resolution of the pneumonic lesion. It is as though at the call of the organism (or nation) fixed or sedentary factory workers enlisted in the capacity of shock troops for the good of the whole.

Sherrington¹² and Cannon¹³ have each advanced illuminating evidence in support of the concept of organism by their masterly demonstrations of the integrative functions of the central nervous system, the sympathetic and the endocrine glands. In the field of psychology the same tendency of contemporary thought to envisage the human psyche as part of the total organism is reflected in the school of "Gestalt" psychology. The writings of Martius,¹⁴ Wertheim,¹⁵ Koffa,¹⁶ and Kohler¹⁷ seem to express an effort to forestall the danger of special schools in psychological research and practice, and so to avoid the pitfalls into which the elemental system of biological thought has led us in clinical medicine.

Studies in human constitution or clinical organismalism which are going forward today, impelled by the first impulse from Hippocrates,¹⁸ began again to emerge vigorously immediately after the close of the great war. Ritter's book appeared in 1919 and in the same year the first publication in this country on the clinical aspect of the subject from the Constitutional Clinic, at the Presbyterian Hospital in New York. In this the following sentence appeared: "The study of the individual dominates and surrounds the study of his affliction, and it is amazing how frequently the particular pathological disturbance belongs irresistibly in the whole fabric of his personality."¹⁹

From 1920 until today the literature on the subject of constitution has grown enormously through contributors from almost every branch of medicine. It is interesting to reflect, consequently, that from the time of Virchow's offering of the cellular theory, to the time of the great war, medicine was powerfully dominated by the elementalist philosophy. Since then, perhaps due to some unconscious integrative trend engendered by the cataclysm of war, the organismal concept has been growing rapidly in the minds of medical men the world over. Perhaps the conflict which

The crash of the great war marked its end and marked the decisive turn of human life into some new direction, as yet not fully understood . . . The prolongation of outworn forms of life means a slow decadence in which there is repetition without any fruit in the reaping of value. There may be high survival power."

With these general remarks concerning the two ways of studying human beings, and having stated that our position is firmly in support of the organismal concept, let us return to a more detailed examination of our problem. (Fig. 2.)

Fig. 2—Schematic Representation of the four Panels of Personality indicating how the Phenotype results from the interplay of Heredity and Environment

has existed between students of constitution in medicine and the present organization of academic medicine is merely the reappearance in another guise of the age-long controversy between the elementalist and organismal philosophies. Constitution study is in reality merely clinical organismalism.

In this connection it is not without significance that Whitehead²⁰ writes in his latest book: "The 19th century was an epoch of civilized advance . . . humanitarian, scientific, industrial, literary, political. But at length it wore itself out.

Fig. 3.—Contrasted Gallbladder and Peptic Ulcer types. (Note rounded contours and feminine expression of the Gallbladder case on the left.)

In our efforts to evaluate the essential quality of the individual human organism, we originally resorted to the plan known as the panels of personality. This involved coordinated studies of the morphology, physiology, immunity, and psychology. Because it was simplest and most obvious, we began with observations on size and shape. Very soon we rediscovered the ancient truth known to Hippocrates that there are two kinds of people: long thin ones, and short thick ones. Looking back from our contemporary position, the figure of Hippocrates perhaps marks the crystallization of the concept "Man, that infinitely variable organism without which human disease is impossible." But that there were differences between individuals of the species was common knowledge long before the great Greek physician pointed out some of the relationships which these differences bore to health and disease. Men recognized, for example, such ex-

tremes as strong people or weak, tall or short, capable or ineffective, cruel or kindly, coarse or sensitive, logical or imaginative. These varying qualities were seen to be combined in ever-changing patterns and the resulting individuals, through the ages, have been roughly classified by a kind of natural or folk feeling about their appearance and behavior. Many classifications of mankind have been presented and the following table shows that they are all based on different names for the same things (Table I).

But clearly, such a designation of type

(Fig 3) Not only did these contrasts hold for the physical form, but also they were correlated with psychological qualities which agreed in general with those described by Kretschmer²¹ (Fig 3). In other words, so far as the long thins and short thick were concerned, classification by the disease potentiality method resulted in the demonstration of the same two basic types as did the direct observation of mankind from a non clinical viewpoint.

But the qualities which definitely marked patients suffering from the other diseases were woven irregularly through the fabric

TABLE I—SHOWING DIFFERENT NAMES FOR THE BASIC HUMAN TYPES

A de Haller (Suisse) 1750 Halle (Francais) 1797	Type thoracique	Type abdominal	Type athletique Type musculaire	Type nerveux et cephalique Type nerveux

based upon morphology is quite inadequate to cover all the many and subtle differences between individuals. It was for this reason that at the Constitutional Clinic we decided to approach the classification problem from the standpoint of clinical medicine rather than from that of anthropology, in the strict sense of the term. Instead of separating human beings into groups on the basis of their form, language, habits, etc., we selected their disease potentiality as the criterion. Thus all individuals with peptic ulcer were subjected to study as one group, all with gallbladder disease as another, and those with pernicious anaemia, diabetes, acute rheumatic fever, etc., into others. There were notable differences in personal identity between members of these different disease groups. Now it is significant that the basic types of Hippocrates were contrasted most sharply in the members of the peptic ulcer and gallbladder groups

of the total personality. Such individuals could not be definitely classified in Hippocrates' groups, although they displayed enough characteristics in common to be quite easily recognized. Finally there are individuals who cannot be classified either in one of Hippocrates' groups, or in our disease races.*

Some of these are frequently designated as one or other of the many forms described by endocrinologists and students of the vegetative nervous system (sympathetic—and vagotonic). These groups of workers have contributed much during the past decade toward the study of the individual. Indeed, in some instances the endocrine balance has been credited with

* The term disease race as we have employed it has been criticized as inappropriate if not incorrect biologically. We have used it to designate a collection of individuals who possess in common a sufficient number of remarkable and similar characteristics to justify grouping them together.

From 1920 until today the literature on the subject of constitution has grown enormously through contributors from almost every branch of medicine. It is interesting to reflect, consequently, that from the time of Virchow's offering of the cellular theory, to the time of the great war, medicine was powerfully dominated by the elementalist philosophy. Since then, perhaps due to some unconscious integrative trend engendered by the cataclysm of war, the organismal concept has been growing rapidly in the minds of medical men the world over. Perhaps the conflict which

The crash of the great war marked its end and marked the decisive turn of human life into some new direction, as yet not fully understood . . . The prolongation of outworn forms of life means a slow decadence in which there is repetition without any fruit in the reaping of value. There may be high survival power."

With these general remarks concerning the two ways of studying human beings, and having stated that our position is firmly in support of the organismal concept, let us return to a more detailed examination of our problem. (Fig. 2.)

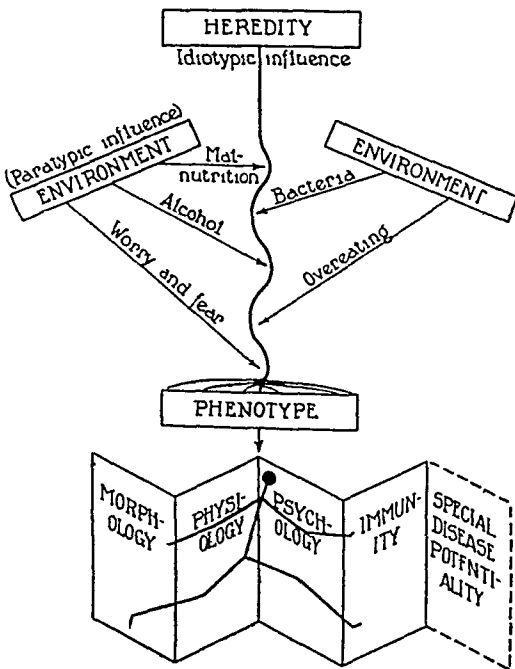

Fig. 2.—Schematic Representation of the four Panels of Personality indicating how the Phenotype results from the interplay of Heredity and Environment.

has existed between students of constitution in medicine and the present organization of academic medicine is merely the reappearance in another guise of the age-long controversy between the elementalist and organismal philosophies. Constitution study is in reality merely clinical organismalism.

In this connection it is not without significance that Whitehead²⁰ writes in his latest book: "The 19th century was an epoch of civilized advance . . . humanitarian, scientific, industrial, literary, political. But at length it wore itself out.

Fig. 3.—Contrasted Gallbladder and Peptic Ulcer types. (Note rounded contours and feminine expression of the Gallbladder case on the left.)

In our efforts to evaluate the essential quality of the individual human organism, we originally resorted to the plan known as the panels of personality. This involved coordinated studies of the morphology, physiology, immunity, and psychology. Because it was simplest and most obvious, we began with observations on size and shape. Very soon we rediscovered the ancient truth known to Hippocrates that there are two kinds of people: long thin ones, and short thick ones. Looking back from our contemporary position, the figure of Hippocrates perhaps marks the crystallization of the concept "Man, that infinitely variable organism without which human disease is impossible." But that there were differences between individuals of the species was common knowledge long before the great Greek physician pointed out some of the relationships which these differences bore to health and disease. Men recognized, for example, such ex-

interesting and effective procedures. Some of these are as old as mankind and have found expression in magic, mysticism and necromancy. Others appear in the later, more intellectual disciplines of the older formalized psychiatry, and in the teachings of Janet, of Mayer, of Jung, and of Freud and the whole school of psychoanalysis. Obviously then, the difficulty of classification exists because man is such a complex animal, and secondly, because he is rarely found today in pure-bred species.

It would seem, then, that there are three more or less general modes which can be applied in the effort to classify the diversified creature Man. First there is the simple division of Hippocrates, and second the patterns supplied by endocrinopathies. These two, perhaps, provide the gross criteria for the existing concepts of racial stocks such as nordic, alpine, mediterranean, negro and mongol. Third, and finally, there is the individual's personal essence which defies classification. This unique quality which I shall designate by the letter "C" because for clinical purposes it is constant, and must be recognized and respected for itself alone. The organismal viewpoint and its clinical expression, constitution-study, consequently can be thought of as the science of the individual. The successful appraisal of any person is greatly facilitated by keeping these three systems in mind. But even with the assistance of these rational concepts, the essential quality often escapes us. It is a subtle thing and sometimes is perceived and rendered best and quite unwittingly by the painter or caricaturist.

In further discussion, then, of this quality designated as "C," one can properly say that the patient who confronts a physician is unique. We know that he springs from two other human beings whose qualities he variously displays, and we can discover the conditions which have surrounded him in life. Yet we cannot fathom in the new individual that certain special completeness of person which cuts him out sharply from the mass and makes him stand apart and alone. This aloofness or otherness, which we have called "C"—is the essence of the new creature. It marks the difference between any two brothers, any two sisters, any two patients, or between the patient and his doctor. While one clearly senses this special otherness of each separate human being, no one

has ever been able, even by the most searching analysis of parts and functions, to capture and prove its quality. The "C" however, does not represent the complete organism. It is like a thread hung in a solution of salts and about which crystals form. Often at first its subtle lineaments may escape us, particularly if gross changes in the physical and spiritual state of the whole person occur.

Thus the completed organism may best be designated as "CV" of which the "V" component is variable. There are certain influences, whose nature we are dimly beginning to see, which may so radically modify the "CV" that its last expression almost totally denies the first. Striking examples of such changes are displayed, for instance, by wellknown endocrinopathies, acromegaly, myxedema, or the virilism of Gallais (Figs 5 and 6). On the more constructive side analogous modifications are seen in those often remarkable metamorphoses which take place at puberty, or following successful glandular therapy. Some of the best illustrations of the latter are found in cases of retarded development due to hypogonad function, or in Graves' disease, or childhood diabetes. From these experiences, or so called pathological examples, there extend in continuous gradation various degrees of changes in "CV." Finally, there are those slight and transient alterations which the layman notices by the remark—"what ails so-and-so, he's not been himself lately."

Yet notwithstanding the changes in "CV"—of whatever degree—there always remains an indelible residue of the original and unique individual "a shadow of his former self,"—the "C." This is the basic personality, containing traces of racial stock, family traits, and the new unique quality possessed by each person. Pende believes that the racial factor is paramount and that no matter what distortions of form, color, or behavior are produced by developmental fault, accident to embryo, or experimental cross breeding, the stock from which the resultant deformation springs is still clearly recognizable. Thus, for example, red or white or purple-eyed *drosophila*, or those with crumpled or absent wings, abnormal abdomen or reduplicated legs, remain irrevocably *drosophila*. Furthermore, it has been clearly shown by the dog breeding experiments reported by Lang and more recently those of Stockard,

that the same principle holds for higher mammalian vertebrates. Thus, as Lang shows, if such widely different types of dogs as Dachshund and St. Bernard are bred together, it is still easy to distinguish through the grotesque confusion of characters in the resultant hybrid creature, the indestructible stamps of both parent races. (Fig. 7.)

The individual otherness which is so tenacious of itself and always appears with equal distinction either anew in the stranger, or continuously in old friend or

beyond recognition. Indeed the fiction of Dr. Jekyll and Mr. Hyde was but the poet's reflection of a natural occurrence. Similar, though slower-moving and more lasting, modifications of human beings are to be seen in various forms of insanity and physical disease. Yet shimmering through extreme degrees of change, the old friend or experienced clinician can always catch the indestructible pattern of the patient's original "C." One has only to remind the reader of the tall slender youth, with dark coloring and silent aloof demeanor who

Fig. 5.—Cushing's Case XXVI. Showing that the acromegalic patients development and which materially aid in diagnosis are no more striking than those visible between the Peptic Ulcer and Gallbladder types shown in Fig. 3.

brother, is a complete thing—a positive force which emanates as a total value. It projects its indissoluble flavor upon us, defying analysis, through a composite of form, posture, gesture, expression, tone of voice, odor, eyelight and turn of mind.

Less easy to define, perhaps, yet no less impressive are those swift and terrible changes in the appearance and conduct of a person who is overwhelmed by a powerful emotion. In the grip of sickening fear, the murderous passion, a transport of joy or religious inspiration, a person's appearance and conduct may be changed almost

does not mix well with his fellows at school. Some years later the shadow of that boy may be glimpsed in the sullen paranoid or rigid close-bent catatonic schizophrenic.

In the sphere of so-called bodily disease a similar picture might be drawn of the large, deep-chested, heavy youth, with very broad, short face, whose blue eyes are set far apart and whose pink cheeks and exceptionally fine, silky hair are the joy and pride of his mother. Yet his rather neutral, gentle, fireless disposition somewhat disappoints her. Many years

later, she or the old family doctor sees the shadow of that florid youth beneath the light, tawny skin, soft flaccid tissues, and pale, lusterless blue eyes of the patient with pernicious anemia.³

The composite of appearances to which reference is made above is common knowledge and mentioned first because it is found, as it were, on the surface or outside of the animal. But there are many other criteria which represent changes within the external envelope of the body and mind. These indirect evidences, such

from the ward, is in her accustomed place because of the strangely sibilant wheeze of her own personal asthma.

It must not be supposed, however, that through inherited factors alone is derived that peculiar difference which isolates the individual from all others. From the moment of special condition under which the egg is fertilized by the sperm, ever changing influences outside the developing embryo and subsequently growing child, act impressively upon it. How much responsibility for the quality of the finished

as, for example, blood-pressure fluctuations, belching of gas, diarrhoea, and complaints of subjective distress ranging from intense pain to the lightest and most fleeting unusual sensations, are called symptoms. Yet even through these supposedly universal phenomena, the friend or family doctor can still detect the indestructible "C." At the sound of his staccato cough, in alternating groups of three and two, everyone in the hospital knows that old Mr. R. is approaching; or that queer Mrs. L., who always sits in the corner, half turned away

person at any given moment of his life (phenotype) should be ascribed to the inherited values, and how much to the effects of environment, is a question which still forms the center of active biological controversy. However, it is not the purpose of this essay to continue that historic discussion. My own belief is in accord with those who grant to heredity the major responsibility, yet recognize the powerful influence exerted by outside forces upon the embryo and developing child. Among the more usually recognized of these may

be mentioned changes in climate, food (vitamin lack), sunlight and altitude (oxygen tension). The application of this attitude to clinical problems is clearly indicated to us by the realization that natural historians have always insisted that it is impossible to think of a living creature apart from its environment. Indeed, the two are so intimately joined that it is no easy task to decide, for example at what stage oxygen from the surrounding air fuses as oxyhemoglobin with the structure of the organism, or when ingested carbohydrate becomes vitalized in the energy productions of mus-

variety of muscle, which is nonstriated, not under conscious control and carries out the vital processes supporting the life of inner existence and procreation. But this type of contractile tissue is strongly influenced by emotions. Yet it is not necessary that the emotions be perceived in consciousness to be effective in modifying the function of organs equipped with smooth muscle. Ordinarily, if the organism is in good emotional equilibrium, the body machinery moves easily at its work, quite automatically and unnoticed by the individual. But if there is a disturbance, no matter

DIAGRAM SUGGESTING STRUCTURE OF THE MAN-ENVIRONMENT-UNIT OR THE WHOLE MAN

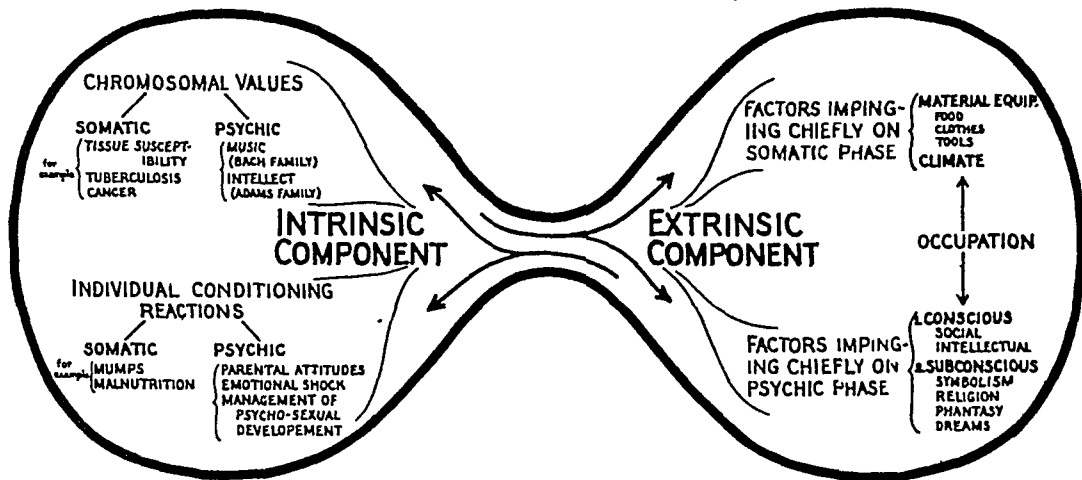

Fig. 8.—Note the arrows representing the flux of interacting forces which form the continuity between living organisms and their individual environments.

cle. Consequently, the investigation of a human being's constitution must include all the gross and subtle details of his environment—it becomes, in effect, a study of the "man-environment-unit." (Fig. 8.) The problem would perhaps be easier if the palpable universe comprised man's only envelope. But because of his imaginative faculty, his phantasy life, another vast imponderable, yet entirely personal universe, supplies an equally complex and poignant environment to which he must likewise make adjustment. To the pressure of the physical world he responds in general with consciously directed muscles. Such muscles are chiefly concerned with the life of gross or spatial relation to environment. The necessary reactions to the impact of his phantasy world are executed by the other

how minute, of the balance between the human animal and either of its two universes, signs of that disturbance are immediately apparent. Consequently, we may accept the thesis that disease is simply the expression of maladjustment between organism and surroundings, an overthrow of the delicately balanced structure termed the "man-environment-unit."²⁷

Now, so far as the doctor's attitude to the patient is concerned, there is no doubt that it should be largely occupied with the forces which have produced the "CV" or total being. As has been shown, the "CV" can be changed almost beyond recognition, but this change seems to be brought about almost entirely in the sphere of the "V" component. The "C" factor, which is the essence of the individual, displays—for the

practical purposes of clinical medicine at least—complete fixity. In illustration of this tenacity, such racial or family characters as the famous Hapsburg lip, may be mentioned; or the muscular genius of the Bach family; and, from the realm of pathology, hemophilia. It is quite evident that no modifying influence from environment has ever made the slightest impression upon these unique hereditary insignia. It will be seen, then, that the representation of the whole man as "CV" one part of which expresses in part his racial stock or heredity, and the other the changes wrought by environment, is in principle similar to Tandler's²⁸ and Bauer's²⁹ idea of constitution and condition, or Sieman's³⁰ idiotypic and paratypic values.

But by whatever forms they may be designated, there can be no doubt that both the forces of heredity and environment, interacting together, produce the man or woman who as a patient stands before the physician. Consequently, perhaps the doctor's most important concern should be their consideration. He should, therefore, be familiar with the general principles of genetics so far as they are now known, with the processes of growth and development, and with the kind of modifying influences which ordinarily flow from the physical and spiritual environment of human beings. Yet when these vast fields of knowledge are expanded beyond those now conventionally covered by physiology, chemistry, physics, and psychology—all relating intimately and fundamentally to clinical medicine—the physician is faced with a superhuman task. To be proficient in any one of those subjects is worthy of a man's life-long and undivided attention. Clearly he cannot be master of them all. Yet each one is germane to clinical medicine. Doubtless that is why specialism has developed in the fundamental sciences as well as in the study and care of disease involving separate parts of the body and mind. As a result, the whole man has been subjected to increasingly detailed analysis, has been divided into many parts, and the concept of wholeness lost. Consequently the physician, whose first interest is with the patient or whole human being, is forced to call upon the knowledge of the special workers. They, in turn, must help him to the utmost in his difficult task of evaluating and managing the individual. These matters which concern the "man-environment-unit" apply equally to the average person,

the genius and the defective, who may or may not become ill. Thus, not only do they logically precede the concept of disease, but they are essential to a proper understanding of its nature.

VAGARIES OF APPENDICITIS

FREDERICK H. FLAHERTY, M.D.

Syracuse

It is generally believed that death from acute appendicitis has increased in late years. Vital statistics tend to confirm this statement; this, in spite of the great improvement in the technic in all surgical procedures. The preoperative and postoperative care, clysis, intravenous use of saline and glucose, and blood transfusions have saved many lives. The literature is voluminous with statistics from many clinics. Much of the literature deals with preoperative and postoperative care.

It is not my purpose to give statistics nor quote the literature on this subject with which most of us are familiar. The author shall endeavor to point out some of the factors that cause confusion and delay in the diagnosis of acute appendicitis. The diagnosis of a typical acute appendicitis can often be made by the patient or one of the family. Many of us have had such experiences and have confirmed the diagnosis upon operation. Nevertheless, the fact remains that early diagnosis in many cases of this disease, even in the best clinics, taxes the ability of the physician and surgeon. What physician or surgeon even with considerable experience in operating for acute appendicitis, can say that he has never missed making an early diagnosis or has operated for acute appendicitis and has found a normal appendix? It can not be done unless his experience is very limited.

In the hands of the well-trained surgeon, mortality in appendicitis does not come from preoperative or postoperative care. It comes from delayed diagnosis either by the attending physician or the attending surgeon and not infrequently by confusion caused by too many different opinions from the staff. Dr. Harold Newhoff of Mount Sinai Hospital, New York City, in a recent article states, and rightly so, "that intra-peritoneal suppuration, and not some distant complication, is the usual cause of death after operation for acute appendicitis." The surgeon or physician, who signs the death certificate in cases of death following operation for acute appendicitis as cardiac failure, renal insufficiency, ob-

struction or even pneumonia (except in unusual cases) is not stating the fact.

Variations in the anatomy of the appendix may be the cause of some of the vagaries of its disease. The circulation of this organ varies greatly in different individuals. A large mesentery with plenty of blood supply appears to be less liable to infection than does the appendix with a short mesentery—a small opening into the cecum will prevent the proper emptying of this organ, thus rendering the appendix vulnerable. There exists in certain strains of the human race a greater tendency to appendicitis than in others. It is not unusual to have three or four children in the same family affected with this disease during young life—on the maternal side the same history even back to the maternal grandparents with no history of it occurring on the paternal side or it may be reversed. In taking the history of a doubtful suspected case of appendicitis, a history of appendicitis occurring in other members of the family is of some importance. Again, the position of the appendix is an important element in the vagaries of this disease. A retrocecal appendix produces different symptoms from the appendix hanging free from the lower end of the cecum. A long appendix running down over the ureter into the pelvis will manifest itself in bladder symptoms. In case the cecum has not descended, occasionally one will find an acute appendix up under the liver. This anomaly is most confusing. An acute appendix may occur in a right inguinal hernia sac. This has occurred several times in the author's experience. A number of years ago he operated upon an elderly man with a strangulated hernia on the left side. Upon opening the hernia sac he found the cecum with an appendix which was mildly acute. This was not a case of transposition of the abdominal organs. However, given a left-sided inflammation in the abdomen with symptoms pointing to the appendix, it is well to percuss the heart and liver to rule out a dextrocardia with transposition of the ab-

dominal viscera. The author has never encountered this condition with an acute appendix. He has suspected it many times when he had opened and found a left-sided appendix due to a mobile cecum or an appendix drawn over to the left by adhesions.

We find that the acute appendix, which is swollen, its peritoneum reddened, the middle layer infiltrated, and the mucosa injected, produces mild but typical symptoms. If not removed, the symptoms subside only to recur usually in a more marked degree. The markedly infiltrated appendix reddened, and often surrounded by omentum just as a mother wraps up a sick child in a blanket, is the type which is apt to rupture if not removed. The appendix which is gangrenous, covered with exudate in areas but not perforated, if properly handled with the least trauma possible and with every effort to limit the contact of its surface to the surrounding peritoneum, can be removed and the abdomen closed without drainage or at most a small strip of rubber tissue drainage down to the peritoneum. The ruptured appendix is apparent with its localized peritonitis or abscess formation. Finally, the ruptured appendix with spreading peritonitis requires the greatest of skill in the removal of the appendix and the care of the peritoneum. It is in this type of appendix that death is most likely to occur from a spreading peritonitis.

It is generally agreed that every diseased appendix ought to be removed. The fact must not be lost sight of that many cases of appendicitis recover without operation, even some that rupture with localized peritonitis with abscess formation with rupture of the abscess into the intestines.

In the past three years the author has had three patients referred to him diagnosed as acute abdomens that turned out to be angina due to coronary disease. Occasionally in patients suffering from pneumonia, especially children, a diagnosis of appendicitis is made. This should never occur. It is due to insufficient history and observation of clinical symptoms. The abdominal rigidity occurring in pneumonia is easily differentiated from the rigidity in appendicitis. The abdominal rigidity occurring in pneumonia is not a true rigidity. It recedes on deep expiration. The location of the tenderness is lacking.

Pyelitis, especially in children, is quite

frequently diagnosed as acute appendicitis and at times is operated upon for such. This should not occur. There is a higher temperature, the blood count is usually higher, and tenderness in the right kidney is present. More important is the finding of pus cells in a catheterized specimen of urine. It may seem trite to emphasize the microscopic examination of the urine. However, in the hurry of a so-called emergency operation this procedure is sometimes neglected. It is more important than the blood count. The thorough check-up on the urine will save an operation on a suspected appendix when the symptoms are atypical and due to the kidney or stone in the ureter. The following case will illustrate how a surgeon or a physician may be confused by the early symptoms of an acute appendicitis. A cystoscopic examination was made on a patient by the urologist on account of the bladder symptoms. The urologist found the right ureter and bladder injected and inflamed, but was not satisfied. Later an acute gangrenous appendix lying across the right ureter down to the bladder was removed. This case is cited to illustrate the vagaries encountered. A retroperitoneal acute appendix, high up in the kidney region, at times is extremely difficult to diagnose. There may be pus and blood in the urine, which certainly would point to the kidney. Fortunately, the urge for immediate operation is not so great. An x-ray will aid greatly in differentiation.

Probably no acute adult abdomen has in the past been more frequently diagnosed as acute appendicitis than perforated gastric and duodenal ulcer. Numerous signs, that we have in acute appendicitis, exist which lead to this error—right-sided rigidity, severe pain and dullness in lower right abdomen, high temperature, and blood count. There is no condition in abdominal surgery in which a more thorough history is needed. If the case is seen early and gives a clear history of ulcer, the differential diagnosis is quite simple. After a few hours with an indefinite history, it may become almost impossible to diagnose.

An appendix, when it has become entirely gangrenous and has not yet ruptured, may deceive the most expert. A college girl suffered a mild attack of an acute appendicitis. The following day her symptoms entirely disappeared except for a slight rigidity. She had a normal tempera-

ture, normal blood count, no tenderness, and from all appearance she was normal with the exception of the slightest rigidity. Upon opening the abdomen a gangrenous appendix was found. This is not rare. It shows how easily one can be deceived.

In the female a salpingitis, especially in young girls, will cause confusion. The history will usually disclose pain in the lower abdomen on either side more disseminated than in appendicitis. The blood count is liable to be higher. The smear for gonococci is of greatest value. Vaginal examination will usually decide this case. Yet it is not rare to see a salpingitis operated for an acute appendicitis.

The differentiation of an ectopic pregnancy from an acute appendix ought not to be difficult. Yet, occasionally this error occurs. The history of the menses, the shock, the tender cervix, the palor, the palpation of the abdomen ought to prevent this error in diagnosis. Finally, if in doubt, the Aschheim-Zondek test may aid in the diagnosis.

Acute cholecystitis at times is confused with appendicitis. The symptoms of an acute cholecystitis—the tenderness just below the free border of the 9th costal cartilage, percussion or palpation of the mass, pain radiating to the shoulder, tenderness about the 10th rib posteriorly, jaundice at times—with a good history make the differentiation usually easy.

An acute colitis located in the cecum may simulate an acute appendicitis. Examination of the stool, the more diffuse tender mass, blood count and temperature with the history ought to suffice to clear up the diagnosis. It is possible to have a fecolith ulcerate through the wall of the cecum and produce intestinal symptoms as in acute appendicitis. Two such cases came

into our service a number of years ago. A diverticulum may perforate and produce a local peritonitis with an abscess occurring on the right side. This may be extremely difficult to diagnose from appendicitis. A Meckel's diverticulum may rupture or the diverticulum may have a fetal remains in the form of a free cord at its tip which may become attached to some other organ in its region and produce an acute obstruction in the right lower abdomen.

Two drugs commonly used by physicians—morphine and cathartics—which should not be used when a diagnosis of appendicitis is suspected, are an important cause in masking the symptoms and delaying the operation. The use of morphine is absolutely contra-indicated until the diagnosis has been entirely cleared. The giving of a cathartic, so commonly done in intestinal conditions, can cause a great deal of damage and at times be an element in the death of the patient.

In this brief summary of some of the various diseased conditions which we encounter in the diagnosis of acute appendicitis, it is quite evident that the surgeon must not only be alert and consider all of the vagaries that may occur but also the possibility of the pathology of other organs. The acute appendix means an acute abdomen with more or less peritonitis. If possible, the source of the peritonitis must be found. Delay and procrastination often mean death. In the more obscure cases, in which every means have been utilized, the exploratory laparotomy in the hands of a trained surgeon must be used. In the hands of a poorly trained surgeon it is an extremely dangerous procedure. A human life may be at stake.

713 E. GENESEE STREET

PENSIONS FOR PHYSICIANS

Amid all the plans, some of them fantastic, for old-age pensions, the physicians must look out for themselves, says Colorado Medicine, for no company automatically pensions us at a certain age or after so many years of service. No faithful doctor of medicine should ever be subjected to financial humiliation in his later years. Our Woman's Auxiliary is aware of the need of something to be done and has already taken tangible steps in that direction. However, the move should be on a scale far more vast.

We have noticed a few articles on this subject in our medical journals. They have shown a few pertinent facts. If 150,000 doctors paid \$1.00 per

month into a fund, it would amount to \$1,800,000 annually. It would provide, say \$100.00 a month to every physician past the age of 65 and half that sum to his widow for life if she survived him. In order to partake of the fund he would have to abstain from practice. This would take approximately 20,000 men from practice to begin with and perhaps 5,000 per year after that. There would be some resultant easing of the "starvation period" suffered by the younger men.

There is plenty to be said pro and con. It must be promulgated through our publications, discussed in our meetings, and criticized by great insurance companies and the A. M. A.

Symposium on The Columbia County Department of Health

ORGANIZATION OF THE COLUMBIA COUNTY DEPARTMENT OF HEALTH

WILLIAM D COLLINS MD

President, Columbia County Board of Health, Hudson

The County Health Unit as it is to day in our county is due to a desire on the part of the Medical Society to place the administration of public health on a more modern and intensive basis. You are all agreed that the health officer of yesterday, even though compelled to be a licensed physician, had imposed upon him duties that were as foreign to his training as possible. In many instances these duties were more or less of a police nature. In some instances the tasks were more or less humiliating to the sensitive and highly educated physician. The health officer was compelled to placard the home of one ill of a communicable disease to fumigate at the termination of a quarantine to investigate complaints of alleged nuisances which in most instances bore no relation whatever to the health of the community.

Early in this century began the campaign against tuberculosis. This was of an educational nature, and the local health officer was the liaison officer through whom the information was to be distributed. Then there followed the campaign against high infant mortality, and coupled with this were the efforts to improve the milk supply of the public. Soon the warfare against venereal disease was started, and with the advent of toxin antitoxin eradication of diphtheria became a part of the duties of the local health officer. Prenatal work then came into the scheme so that it soon became evident that the local health officer was burdened with tasks, none of which were light.

He was, of necessity, a part time official most inadequately compensated for the many and varied duties asked of him. Now the mere placarding of a home in which

there is a communicable disease, is not sufficient. An intensive epidemiological study of the case must be made, contacts sought, and missed cases found. The field became too large for any accomplishment if the old unit of town and village boards of health were continued, and so the only logical and workable unit was the county with a full time, well compensated Commissioner, and a staff large enough to give every section of the county equal service.

The medical profession has always participated in the actual performance of the work of preventive medicine, and so, because our Society realized how futile it was to hope for any success in this ever growing field of public health under the old regime, we petitioned our Board of Supervisors to create a County Department of Health. We felt that a centralization of all public health activities would work to the benefit of the public and the physician alike. We insisted however, upon one provision, and that was that it be kept strictly under local control. I, for one, believed that a properly functioning department of health would be the greatest check upon the entree of any form of socialized medicine, of which we hear so much to day.

It is a fact that it is necessary to provide services to the indigent, that they are unable to procure of their own accord, namely, diphtheria immunization, smallpox vaccination, chest examination and tuberculin skin testing in many instances, prenatal service, and care for the venereal diseases.

The providing of this indiscriminately, and without proper investigation as to the financial status of the individual, is indeed a wedge whereby state or socialized

medicine can gain a foothold, unless it is done under some plan which protects the physician and excludes those able to provide for themselves.

The scheme being worked out in our Department, and which will be explained to you to-day, will, I am sure, appeal to you as being of benefit to the indigent, and not in any way interfering with the practice of medicine. On the contrary, I feel that the physician is greatly benefited by our plan.

Prior to 1933, Columbia County spent for health work, including the maintenance of the tuberculosis sanatorium, a sum in excess of \$80,000 annually. Taking the year 1931 for example, the net maintenance cost of the sanatorium was \$62,000. The other health activities were at an expenditure of approximately \$20,000. We had at that time two county health nurses who were responsible to the Nursing Committee, appointed by the Board of Supervisors; one tuberculosis nurse working under the direction of the Superintendent of the sanatorium; one public health nurse in Chatham, employed by the village Board of Health; and one public health nurse in Hudson, directed by the health officer of this city. The salaries of these approximated \$9,000. Then, there were 23 town and village health officers, whose aggregate salaries amounted to \$6,000. Traveling and other expenses brought the total to \$20,000. There was no coordination in the efforts of these workers, though all were aiming for the same ultimate end. They were responsible to as many different boards and commissions as there were employees, and all were working independently of one another. In many instances, the duties of one overlapped those of another.

Under the new plan, however, there is a centralization of all activities with the work well coordinated, and the county thoroughly covered. When the Board of Supervisors formed the Department of Health for the county, and the city of Hudson agreed to participate, a new era in public health was inaugurated here. The Board consisted of seven members, three of whom were members of your Society, and all were enthusiastic for the work about to be undertaken. It was our effort to retain the good will of the medical fraternity of the county, as we knew that without the co-operation of these men, it would eventually fail.

The selection of a Commissioner became our first duty. We were desirous of selecting a local man, if one were available with the required qualifications, who would know the county and its problems, and work for greater harmony amongst all. Just here, I wish to express our gratitude to Dr. Godfrey of the State Department of Health for the invaluable assistance he gave us in having the Public Health Council accept the qualifications of our local candidate, Dr. Louis Van Hoesen, of Hudson. Immediately upon their acceptance of his qualifications, we appointed Dr. Van Hoesen as Commissioner of Health. The fears of some members of the County Society were immediately dispelled by this appointment, for it seemed to them that we would be dictated to in our selection.

Dr. Van Hoesen immediately began effecting a working organization. He appointed a part-time deputy; he took over all of the public health nurses working in the county, dividing the county into five districts and assigning a nurse to each district; a milk and sanitary inspector was appointed; and actual functioning of the project was soon under way. To the office secretary was assigned the duty of the vital statistics' compilation.

The tuberculosis work, including the sanatorium management, was a part of the activities of the newly created Department of Health.

Now, the health activities came under one head—the Commissioner—and he outlined a program that was satisfactory to the medical profession, and likewise to the lay people. The production and distribution of milk was put upon a modern and scientific basis; case finding in tuberculosis became a part of the nurses' duties; communicable diseases are investigated immediately, and the source of the case sought; venereal diseases treated in the indigent, and those financially able to provide such treatment themselves were directed to their own physicians. Immunizations against diphtheria and smallpox are done under a plan agreeable to the medical men; and prenatal care is given to those in need of such. All those benefiting by this work are investigated as to their economic status before any service is rendered.

Let us state the actual cost to the county. Taking the year 1931 as an example again, the county spent \$62,000 for the maintenance of the sanatorium, and \$20,000 for public health work in the various towns and

villages and one city, making a total of \$82,000. The appropriation asked for by the County Board of Health for the year 1933 was \$100,000. This included maintenance for the sanatorium. The organization of the Department and the purchase of the necessary equipment was in itself a capital expense, but at the end of the year a small balance was turned back to the County Treasurer. Disregarding the amount returned, and considering only the \$100,000, when you realize that state aid to the extent of 50 per cent, or \$50,000, was furnished, the actual cost to the taxpayer was \$50,000.

Again, to use 1931, we can show a saving to the taxpayers of a difference between the \$82,000 spent that year, and the \$50,000 in 1933—a saving of \$32,000 for a better and more intensive, and more thorough health service.

Unfortunately, time does not permit me to relate the several instances in which epidemics, particularly of scarlet fever, were abated by the prompt and thorough investigation by the Commissioner of Health in several of the townships and school districts of our county.

CONCLUSIONS

1. Since public health and preventive medicine is an integral part of the practice of medicine, and always has been, it is

our duty to take the initiative in all matters pertaining thereto.

2. Centralization of public health activities is the only efficient and economical method. In a county such as ours, the only logical unit is the county.

3. With state aid, a financial saving and a better service is given to the citizens.

4. The propagandists for socialized medicine, of whom there are many, are to my mind checkmated in a county in which a County Department of Health exists.

5. Participation in health work by the Medical Society as a whole and the physicians, individually, and harmony between them and the public health officials, is a requisite for success, both the physicians and the laity benefiting.

In conclusion, may I express the appreciation of our Board to the Third District Branch for giving us this opportunity of presenting our subject at such a gathering.

To the Columbia County Medical Society I extend to you the thanks of our Department of Health for the cooperation and interest which is making the venture a success.

May I also add our kindly feeling to the State Department of Health which at all times has been most willing and helpful in our problems.

360 WARREN STREET

RELATION OF COLUMBIA COUNTY DEPARTMENT OF HEALTH TO THE PHYSICIAN

FRANK C. MAXON, M.D.

President of the Columbia County Medical Society, Chatham

The relation of the county health unit to the physician is that of the relation to him of any public health organization. It would be impossible in the time allotted to this discussion to go into all the public health activities relating to the practice of medicine.

In this County, the question of the establishment of a County Health Unit was first brought before the County Medical Society some four or five years before its final inauguration. The Society was in favor of the County Unit, first because it felt that health service could be better carried out by full-time men adequately paid than by the old system of health officers spread

throughout the County and receiving such a small salary based on a per capita tax that they could not afford to give health work the necessary time and attention. Secondly, because better service could be had at practically half the cost of the old system.

However, it made stipulations that the personnel of the Unit be filled by County men if they could qualify; that the amount to be appropriated yearly for carrying on the work of the Unit should be under the control of the Board of Supervisors, and that the County Sanatorium should be placed under the control and management of the County Department of Health.

These stipulations were made, first, because the Medical Society felt that any of its members who wished to, and could, qualify would be amply able to carry on constructively the administration of the Unit. Secondly, because if the amount appropriated every year was under direct control of the County Board of Supervisors, it would be able to limit the amount so expended, and, thirdly, because the preventive measures, the control, and treatment of tuberculosis occupies such an important place in the health program it seemed necessary that the sanatorium be made a fixed part of the Unit. These facts are mentioned only to bring to attention the interest in, and the attitude of, the Medical Society toward the creation of the County Unit. This County Medical Society has practically underwritten this County Unit.

In discussing the relation of this Health Unit or any public health organization to the physician, there are three important factors to be considered. First, the plan and scope of public health administration; second, the public; and, third, organized medicine as it exists to-day in the Medical Societies.

The previous paper has given you a very clear picture of the vast field of medicine covered by a Department of Health—the control and prevention of certain communicable diseases, the control, prevention, and treatment of certain infectious diseases, the care of the child and mother, prenatally, natively, and postnatally, the practice of orthopedic surgery, the prevention of tuberculosis, and because of its special nature, special institutions for its control and treatment.

The vehicle for the administration of all these branches or divisions is the Public Health Clinic, supervised by the Department and ministered to by that most important of all the contacts between the public and the Department of Health, the public health nurse.

The second factor is the public. For the purposes of this paper, the public is classified in four groups: First, the indigent; second, those who can afford to pay for their medical service; third, groups interested in health insurance; and, fourth, individuals, groups, and foundations whose purpose it is to furnish free medical service to the public.

The poor we have always with us. They

are perhaps most subject to the ills that befall the human race and they must be cared for for their own welfare and that of society at large. Public health in its present aspect has been practiced for so long a period that not only the laity but the medical profession itself has become accustomed to taking an erroneous viewpoint in regard to furnishing medical service. It seems that a sensible way to look at this question is the way in which the furnishing of any other of the many human necessities would be looked upon. When food, clothing, houses, light, heat, and legal services are given to the poor, the State does not go into the business of raising or producing foods, or mining coal, or manufacturing clothing and building material. These commodities are bought at the market price, or nearly at the market price, depending of course on the amount purchased, from those concerns which are already in the field producing these articles. Why would it not be consistent to feel that medical service should be purchased for this purpose, not from organizations which have sprung up over night, but from that profession which for generations has specialized in the treatment of disease and has spent many years and large sums of money in preparation for its life work? Regarding legal services, no one ever dreamed of setting up a county legal department for the sole purpose of dispensing legal service to the poor. The legal profession has been too well and too intelligently represented in our legislatures to allow any such laws to come into existence. If the prisoner at the bar is unable to provide counsel for himself, the court appoints an attorney to represent him at a substantial fee. You will wish to call my attention to the judges and attorneys attached to the different courts, county, state, and federal, receiving salaries from public funds. I look on these as administrative officials and in the same class as the properly placed officials of a department of health.

Please understand that I do not cite the legal profession to criticize it in any manner. I commend it for its years of activity in protecting its rights and prerogatives. I would suggest the same type of clear thinking on the part of the medical profession. It does not seem to me to be a very difficult problem to work out a plan by which organized medicine will furnish

public medical care and at a fair and reasonable fee.

It should be stated here that the medical members of this Board of Health have taken great pains to see to it that the field of medicine has not been unnecessarily trespassed on, and they are ready to go further as rapidly as the profession at large is willing to assume the responsibility for the rendering of health service.

The second division comprises those who can afford to pay for their medical service. Democracy makes a clear distinction in leaving to private management all business subject to the law of competition. It would not seem to be a sound business principle for organized public health, financed by public funds, to furnish free medical care to those who can afford to pay for it, competing with the medical profession and making serious inroads on its income.

Only a casual survey of almost any public health clinic will demonstrate to what a large extent we have encouraged those able to pay to take advantage of this free service and have perhaps unwittingly so undermined their pride and sense of good citizenship that we have in reality pauperized them. This situation emphasizes how far we have strayed from those old-fashioned American ideals and traditions which were so potent in making our country what it is to-day. Let us encourage an early return to them. Those who can pay should pay for their medical service just as they pay for other services.

Groups and governmental agencies interested in health or sickness insurance. Is there really anything definite in the public mind in regard to launching the scheme of sickness insurance? In the latter part of July, President Franklin D. Roosevelt, in a radio address, indicated his interest in so-called economy security, and shortly afterward appointed a committee under that name and of which the Secretary of Labor, Frances Perkins, was made Chairman. On August 13, Miss Perkins, enlarging on the views of the President, stated in substance, that while some provisions are made for medical and hospital care for indigents, they do not begin to meet the needs of the situation and therefore the Committee of Economic Security was developed to work out a plan to solve the difficulties.

In another article, published August 19,

Harry L. Hopkins, Administrator of the FERA, discussing unemployment insurance, says: "In this bailiwick of public welfare lies also another aid to secured life—health insurance with medical care. All these things can be achieved with only minor disturbance to the present pattern. With private hospitals financially distressed, doctors on relief, sick people foregoing care, and a national crop of tuberculosis and rickets sown and ready for harvest a few years hence, people are beginning to realize that the problems of health coexist with economic disruption. So this becomes a logical objective for any commission charged with public welfare."

During the special session of our legislature, Governor Lehman expressed much interest in some form of health insurance. So the effort to institute some such form of insurance is well under way without the slightest suggestion that the medical profession is to be consulted as to how the medical care will be furnished. Financed and fed by the laity, the nature, scope, and method of medical treatment ordered by lay groups, with the same authority, presenting and discharging patients, is far too foreign to the medical viewpoint to ever be tolerated by the profession. When these measures are finally mapped out, the medical profession should have at least one foot under the conference table.

As for groups and foundations, their place in the health program is second to none. Vested with vast sums of money to carry on experimentation and research on a large scale, the fruits of their efforts have placed in the hands of the medical man the most valuable ammunition for the cure and prevention of disease. They are the munition plants. In time of war the munition worker does not use his product himself. It is passed on to the man on the front line, and in this war on disease and its prevention, the front-line man is the practicing physician. Then, and hardly less important to the vigorous campaign for better health than is the research work, comes that of public health education. He who has had much to do with health work must admit the general ignorance of the public in regard to health matters, and even these large foundations with their ample financial backing and excellent personnel would be taxed to the utmost to carry out anything amounting to a comprehensive program of health education. Theirs to

make the ammunition; ours to fire it. Theirs to educate the public; ours to meet the inspired demand.

We now come to the last and most important factor in the relation of public health to the physician—the Medical Society. The Society is our organized body. On its vigorous activity we must depend to retain such privileges as we enjoy to-day and the hope of entering a wider field in the future. The success we have will in turn depend on the unselfish sympathy and support of each member. The individual physician's attitude toward his society and in regard to health matters is of vital importance.

For generations, the practice of medicine has consisted in the treatment of disease with little or no attention given to the maintenance of health. By this type of practice the physician made his livelihood and it evidently never occurred to him that the practice of measures to maintain and better public health were more dramatic and sensational and equally remunerative.

He, however, was not alone to blame for this custom. The medical schools have always stressed the study and treatment of disease and have nothing or very little in the curriculum in regard to health service. Both these forces, the physician and the school, have educated the public in the belief that the physician's services were to be sought only in case of illness and not for guidance to health.

What measures can be taken to return to the physician a field that he never should have allowed to slip from his control? Several plans are already being carried out in the counties and cities of different states. They strive among other things to

make every physician's office the center from which public health knowledge and preventive treatment can be had and paid for in part from public funds. These plans admit, and I am sure you will agree, the necessity of public health administration but they go a step further and state that the active entrance of the physician into health work should not in any way curtail appropriations for carrying on its work. I disagree with this idea. If the physician enters actively into public health work it should be possible to cut down considerably the personnel of the department, and if he is paid in part from public funds, the appropriation to the department should be reduced to such an extent that the public will not pay twice for the same service. Eventually, the functions of a department of health would be administrative, and the exercise of such police powers compulsory to the protection of society.

What can be done in regard to the adequate provision of health service to permanently establish the medical man in the confidence of the public? A closer organization, a willingness by conference and study to qualify for health administration, an earnest appreciation of his responsibility, not alone to his own private practice, but to the public at large in regard to health matters? This would seem to be nothing more than his honest duty.

Schooled in the etiology of disease, no other group in society is so qualified to render measures for its prevention and treatment.

Versed in the functions of the normal body, who can better teach the lessons of health. The responsibility is ours. We should assume it.

A MODIFICATION OF THE DETROIT PLAN IN ADMINISTERING PUBLIC HEALTH

LOUIS VAN HOESSEN, M.D.

Commissioner of the Columbia County Department of Health, Hudson

In presenting a brief description of the plan which is now being applied in Columbia County in securing the participation of the profession in public health activities, we have no phenomenal discovery to describe. But rather, we hope to inspire increased interest in the field of preventive medicine and wish to develop a

system which will work efficiently for the promotion of public health and at the same time return a satisfactory income to participating physicians.

Reviewing the methods of introducing and applying the new measures of preventive medicine as they have developed in the past, we must agree that all the procedures

pertaining to disease prevention and control have been at all times available to every physician; and also, that early general adoption and application of these methods would have forestalled any need for free clinics.

Since the public must be instructed concerning the value and need of many preventive measures and physicians were not in a position to appear as instructors urging the people to come for such services without appearing in a false light as soliciting work, it became necessary to organize so-called "educational clinics." These institutions were able to demonstrate to both physicians and the public the invaluable results obtainable through carrying on this work. That smallpox vaccination, diphtheria immunization, child-health supervision, and prenatal care are well-recognized procedures, available to every physician, and possessing such value as to demand systematic application, we are all aware.

That these measures have not been generally applied, is a regrettable fact; and that the medical profession has thus failed to develop a source of income is partly chargeable to their own oversight.

One great advantage of a unified health department lies in its opportunities to organize and systematize these functions of preventive medicine.

The Detroit plan is announced as a method of securing participation in public health work by the profession. It actually substitutes the private physician for the health staff worker and socializes preventive medicine by providing a nominal fee schedule which is lower than a reasonable rate, and paid from the tax budget; also encouraging all who so desire to receive treatments at public expense. Somewhat over 80 per cent of Detroit physicians have agreed to work under this plan. What happens to the fee schedule of the other 20 per cent can be imagined. And how soon will be adopted the tendency to place curative medicine upon the same system of reduced fees at public expense, only a socialized people can determine. Vaccinations and toxoid treatments at 50 cents, if paid from public funds, or one dollar if the patient chooses to pay, must be compared with the return obtainable where all pay regular fees if able and the health department provides service for the very poor or those on relief.

In the clientele of each physician, there are many families who still retain their

individual independence and self-respect by continuing to pay their family physician his regular fee; and placing these people into a system of socialized medicine by any act of ours would be a foolish policy. There are also numbers of people who are at present supported by relief funds and while a staff of health workers are available, no doubt a considerable portion of these persons should receive preventive treatments at free clinics from economic considerations.

Separation of individual families into two groups—those independent Americans who choose to select their own doctor and pay him; and those from the socialized beneficiaries who never did pay and never will—is a fundamental idea of our plan. This separation can best be performed by the doctors, whose past experiences furnish the required information.

The plan adopted in Columbia County was first submitted in outline to the Columbia County Medical Society in May, 1934, where it was favorably received.

It was then developed through the following steps:

1. Census of all preschool children in county.
2. Checking census with completed records of immunizations and death records.
3. Lists mailed to each physician requesting him to select any to be referred for free service, and also asking reports of completed work, so that the efficiency of this system could be determined.

The result of this census and canvas indicates that the physicians of Columbia County and vicinity prefer to remain responsible for immunizing, vaccinating, and supervising the health of 37 per cent of all preschool children thus leaving 63 per cent who must depend upon free service rendered by the staff of our health department.

Reports of financial returns to the men who have thus far supplied such information indicate that regular fees have been obtained for nearly all immunizations and vaccinations performed by private physicians; that our efforts to create activity in this work by sending out lists and notices have resulted in many paid immunizations by local physicians in families who would otherwise have neglected to secure treatment; and that our continued efforts to establish annual health examinations, child

health supervision, etc., must permanently increase the income of the medical profession, where willing participation is obtained.

In addition to the previously named procedures in which we solicit the aid of the medical profession, there remain several other functions which have been developed more or less by health workers.

Of these, the annual health examination, we believe, should be delegated entirely to private physicians, and these examinations should be urged upon every family with the purpose of securing diagnoses and treatment for cancer, Bright's disease, diabetes, anemias, etc., while still in the early stages. Our nursing staff is instructed to urge this service.

On the other hand, any case-finding program in tuberculosis, where large numbers are given skin tests, as in high school groups, can obviously be done much more conveniently where such groups are assembled; and the follow-up with x-ray and physical examinations can best be done by a specialist in the work.

The findings of these campaigns are referred to the physician, and his participation and support invited in carrying out treatment if needed.

Venereal disease clinics are held and attended chiefly by patients who have been referred by physicians. An improvement in this work is still obtainable through physicians reporting to the department the names of any persons who have discontinued treatment while under the physician's care. In these cases action will be taken to compel return to doctors' care.

Examinations of food handlers, which were included in the Detroit Plan for participation or substitution in health activities, have not been included in our system for the following reasons:

1. The laboratory and the microscope, rather than the stethoscope provide the facts needed.
2. The private physician could ill afford to accept a fee for reporting a condition which would disqualify a food-handling patient for this job.

We believe all needed examinations for food handlers should be made by a health department official.

The medical profession has expressed rather strongly its disapproval of free clinics. Where these clinics can be con-

fined to immunizations, and preventive and diagnostic work among groups selected by physicians and referred for specific forms of examination or treatment, the objections to free clinics seem to be removed.

We believe the profession should endorse this work under these conditions, thus displaying a real interest in securing such services for those who are unable to provide for themselves.

Furthermore, we believe that such an attitude will justify an organized opposition to the introduction of any health insurance system.

If health insurance really insured health, the medical profession could give it consideration; but we know too well that governmental control means political control, and the less of it we tolerate in the practice of medicine, the better will be the health of the population.

Furthermore, we believe that a majority of the general public would still prefer to purchase their own medical services and deal directly with their own doctor, rather than be assessed or taxed to support a system under which they would be treated by politically appointed physicians, subject to such codes or rules as the dictators in power might establish.

CONCLUSIONS

Summarizing the details of the system which is in operation in Columbia County, there seems to be evidence to sustain the following conclusions:

1. The tendency to encourage socialized medicine is avoided.
2. The private physician is supplying preventive treatment for a large group of individuals who would never attend free clinics.
3. The medical profession better understands that the purposes of a health department are to get real results and to avoid intruding into the field of private practice.
4. Financial returns and established fee schedules, both for the present and, still more important, for the future of medical practice, are satisfactorily retained.
5. The cost of providing the considerable amount of free service is economically provided, without introducing political or bureaucratic factors into the practice of medicine.

HIGH- AND LOW-POWER ROENTGENOGRAPHIC DIFFERENTIATION BETWEEN DIVERTICULITIS AND CANCER OF THE SIGMOID

WILLIAM H. STEWART, M.D., and H. EARL ILLICK, M.D.
New York City

Contrary to a rather general belief, the roentgenographic differentiation between diverticulitis and cancer of the sigmoid is difficult and exacting to make. A lesion of the colon, especially the sigmoid, is probably missed more often than any other in the gastro-intestinal tract.

When a patient is referred to the roentgenologist for an examination of the colon, especially if there is any question concerning the sigmoid, it is important to obtain as much clinical information as possible. Particularly is this necessary when the question arises as to whether we are dealing with a benign or malignant lesion. We have to consider the age and type of the individual, the character of the attacks and whether there has been intestinal obstruction or not, how much pain and fever the patient has during the attack and just what the blood picture is during the febrile period. Has the patient had bloody stools with mucus or frank rectal hemorrhage? What has been the character of his constipation, if any, and has he ever had "explosive" stools. Have the attacks been accompanied by shock and evidence of an acute abdomen and is a tumor present which entirely disappears between the attacks? Has there been any indication of bladder irritation?

The authors have endeavored to answer these queries by tabulating the clinical picture of cancer as compared with diverticulitis of the sigmoid.

One occasionally finds malignant degeneration in a diverticulitis, but the characteristic picture of either, roentgenographic and clinical, then becomes obscure. Anemia out of proportion to the rest of the clinical picture may be found in cancer of the ascending colon but is generally slight in malignant involvement of the distal colon. The first attack of a sigmoid lesion is usually more puzzling to decide clinically than after a long duration of symptoms.

Proctosigmoidoscopy should always be made before the case reaches the roent-

genologist, as barium particles often interfere with clear visualization of the mucosal surface. Unfortunately this type of direct examination is often of no aid due to inability to insert the tube up far enough on account of redundancy. When positive observations are possible, the x-ray can outline the extent of the lesion and define the upper borders.

Having obtained as much clinical aid as possible, one may proceed with the preparation of the patient for the roentgenographic examination. The colon must be empty before giving the barium clysma and this is usually accomplished by giving two ounces of castor oil the night before the examination, followed by a thorough cleansing enema in the morning to be repeated until the return flow is clear. The patient may have a light breakfast and then reports to the roentgenologist for examination. He is placed in supine position on a fluoroscopic table and the procedure is explained to him in order to obtain his confidence. The success or failure of the entire examination may depend on how completely he will be able to cooperate in his ability to suspend respiration while the roentgenograms are taken.

There are certain technical factors of importance in the roentgenographic examination of the colon which might be mentioned at this time.

It is advantageous to have an apparatus which is capable of switching from a fluoroscopic setting to radiography instantly as during fluoroscopy one often observes something which is necessary to record on a film. The filling of the colon is often more complete during administration of the clysma than after turning the patient prone. Fluoroscopy aids one in best positioning the patient so that redundancy is eliminated.

A few words about the fluoroscopic setting may not be amiss. One so often hears a warning not to exceed a certain setting for fluoroscopic use for fear that the patient or operator will receive a "burn."

The opposite is also a possibility—that not enough current will be used to properly visualize the organ being examined and pathological involvement will be overlooked. The fluoroscopic screen may be old and the image not clear or the eyes may not be thoroughly accommodated. The difference when the roentgenologist is properly prepared will be amazing and the added detail obtainable most gratifying. If the films obtained consistently reveal lesions not readily discernible fluoroscopically, it behooves the roentgenologist to locate the trouble in his fluoroscopic technic or apparatus.

X-ray examination of the sigmoid area presents certain inherent difficulties which if not recognized and a technic evolved to cope with them may interfere with satisfactory visualization. The lower colon is commonly freely movable, redundant, and often coils upon itself. It is situated deeply and surrounded by the pelvic walls so that it is almost impossible to directly palpate it. These difficulties can be eliminated largely by administering about one pint of the barium solution, then stopping and thoroughly fluoroscoping the patient in *all possible angles, especially obliquely* so that the entire sigmoid area may be closely examined. At one certain best oblique angle the sigmoid is elongated and clearly visible throughout and the redundant, overlapping bowel shadows are eliminated. It is really remarkable how clearly the entire pelvic colon may be shown in this manner. Since only a pint of the clysma is given, it is not sufficient to fill the upper colon, cecum, and terminal ileum and cause overlapping shadows from this part of the proximal bowel. After the lower colon has been thoroughly examined and roentgenograms made, the entire large intestine is filled to full capacity and the usual stereoroentgenograms made. The patient is further examined after partial and complete defecation.

One matter of considerable importance had better be gone into at this moment. There is one lesion of the colon frequently shown as soon as the colon is visualized. We are referring to diverticulosis. This is often a chance finding of little clinical significance. But there is another kind of case in which it is of utmost importance to know whether diverticulitis is the cause

of the patient's complaints or whether it is a more serious disease. We are now thinking of the obviously very sick individual with some degree of obstruction, fever, and a palpable mass; the barium clysma often shows complete obstruction of the colon in the sigmoid area. Clinically the case may be suspected to be a cancer, and in fact this is often the roentgenologist's suspicion. Should this case be reexamined the following day, it is often one's good fortune to find several diverticuli outlined, and a diagnosis of a benign diverticulitis can be made. If there is too much haste, these cases are sometimes operated upon under the erroneous impression that the completely obstructive lesion of the sigmoid is cancer whereas at operation the tumor is found to be inflammatory; the roentgenologist may save an operative procedure if he counsels waiting for a day to permit reexamination and give the inflamed sacs an opportunity to fill with barium.

Mistakes in roentgenological interpretation often result from trying to do too much; taking care of too many cases in a given time; being too hasty where more time was necessary; as well as in lack of judgment. All of these factors make a correct diagnosis in disease of the colon a difficult matter unless sufficient time can be devoted to the thorough study of the case, just as one knows it must be done when the stomach and gallbladder are examined.

One of the greatest aids in the diagnosis of the lesion has been the minute study and analyzing of the finer details of the roentgenographic appearance. Our method which we now advocate is one suggested by Dr. L. G. Cole in his paper on "Malignancy of the Small Intestines," which was read before the American Congress of Radiology in Chicago in 1933. This method consists in magnifying the image of the involved part of the colon so that all of the finer shadows are brought out in great detail. This magnification of the image we have designated as a "high-power" roentgenogram while those films taken under ordinary technic and which are used for comparison are called "low-power."

These finer details of pathological structures are brought out in a striking manner by roentgenograms of the sigmoid taken with the patient turned obliquely. The

best delineation is obtained when *compression* is possible over the lesion at the time of the exposure of the roentgenogram.

An effort was made to analyze the roentgenographic characteristics of the filling defect in diverticulitis and cancer. Table I summarizes our observation.

The earliest manifestation of diverticulitis roentgenographically is a peculiar, serrated edge to the lumen of the sigmoid. This may vary from a slight saw-tooth, irregular, slightly fuzzy margin to a picket-

clinical appearance in certain stages, which, however, more often is less acute. The duration of the illness may be less than with a benign lesion. Bloody stools are more common and the change in the bowel habits is likely to be more pronounced. There may be expulsive stools or a history of recurring attacks of diarrhea with alternating constipation.

The roentgenographic appearance in cancer is likely to be more definite and decisive. One looks for *canalization*, a

TABLE I.—CLINICAL SIGNS

Cancer of the Sigmoid	Diverticulitis
(1) A disease of advanced years, although it may occur at any age. Apparently attacks all types of individuals. Frequently accompanied by loss of weight.	(1) Most common over the age of 40. Occurs most frequently in obese patients. Seldom loss of weight.
(2) History of a progressive lesion without remission. May have no symptoms until obstruction occurs.	(2) History of recurring attacks over a period of years.
(3) Patient may have but slight or no pain, no fever, and blood count very little effected.	(3) Pain, fever, and blood count indicate acute lesions.
(4) Frequent bloody stools with mucus. Frank rectal hemorrhage at times.	(4) Seldom hemorrhage—occasionally blood streaked mucus, rarely frank hemorrhage.
(5) Increasing constipation with expulsive stool from obstructive lesion.	(5) Constipation recurring with no specially expulsive stools.
(6) Seldom ruptures into the perisigmoidal structures. Only causes "acute abdomen" when producing intestinal obstruction.	(6) Often appears as an "acute abdomen" with considerable shock, whether there is a rupture or not.
(7) Tumor never entirely disappears, although it often diminishes in size.	(7) Disappearance of the tumor.
(8) No special bladder symptoms.	(8) Bladder frequently involved with irritative symptoms.

fence, characteristic appearance. No diverticuli may be demonstrable as separate, isolated sacs, but by the above described characteristics one knows that the condition is present nevertheless. The diverticulitis may be limited to the wall of the colon, the sacs being altogether confined within the layers; there may even be tumefaction and a palpable, sausage-like tumor easily palpable. Such a patient may present an alarming clinical appearance with considerable fever, profuse perspiration, extreme pain and a history of bowel difficulty and increasing constipation, with pain on defecation. The patient demands quick relief and the surgeon may be momentarily confused and uncertain whether he is dealing with an "acute abdomen" or not. Too often his one thought is that it must be a cancer. If the roentgenologist can be positive of his findings and correctly interpret the obstructive lesion, medical treatment may effect the cure. These lesions respond readily to light doses of x-ray therapy.

The cancer patient may present a similar

spool-like deformity of filling, a sharp cut-off between the normal bowel and the diseased portion, with narrowing in the diseased area, the margins of the region being "*fingerprinted*," and the mucosal pattern destroyed. The lesion is *permanent* on all films, does not shift positions and is the same on repeated examinations. The bowel may be dilated abnormally on *both* sides of the lesion. The involved area is fixed in position as though cemented fast, and a palpable tumor may be felt; the area is usually tender. The *location* of the lesion is important in the differentiation. If the defect appears proximal to the free sigmoidal loop, the chances are that it is malignant. Diverticulitis has a tendency to limit itself to the sigmoid, seldom involving the lower portion of the descending.

In studying roentgenographically the differential distinctions between diverticulitis and cancer, it is helpful to tabulate the more important roentgenographic findings. By careful deduction and comparison we may then be able to arrive at a satisfactory

pathological classification. We have found Table II useful.

In some cases no matter how much care is used, there will be a redoubling of the shadows and the lesion will be covered up. In one patient we were able to demonstrate the cancer by filling the bladder with

looked or filling defects caused by intestinal contents excluded. It is a frequent occurrence to find a renal or gallbladder lesion which accounts for the entire clinical picture when the patient is referred for an x-ray examination of the colon. It is well, also, to become accustomed to a variance

TABLE II.—ROENTGENOGRAPHIC SIGNS

Cancer of the Sigmoid

- (1) Canalization always present in certain types.
- (2) Mucosal pattern destroyed.
- (3) Filling defects show as lobulated cauliflower masses with irregular ragged lumen and showing finger print deformity.
- (4) There are two special types, the napkin ring deformity with minimum involvement and the massive deformity with crater formation.
- (5) Usually a sharp sudden demarcation between the normal and pathological involvement.
- (6) Haustral markings destroyed.
- (7) Persistent unilateral deformity in some types.
- (8) No evidence of diverticuli.
- (9) Constancy to the character of the deformity.
- (10) Rigidity with fixation and a frozen mass.
- (11) No masses of barium seen outside the lumen of the gut.
- (12) Usually intraluminal unless accompanied by perisigmoidal inflammatory mass.
- (13) The sigmoid is liable to maintain its patency through canalization and fixation. The proximal colon is dilated. Sudden obstruction may occur.
- (14) Spasm of the colon is less frequently seen in malignancy.

Diverticulitis

- (1) Not present.
- (2) Mucosal pattern still incompletely seen.
- (3) Filling defect consists of a serrated irregular "picket fence" appearance.
- (4) Massive involvement. No crater formation. Never napkin ring deformity.
- (5) No distinct demarcation between normal and pathological involvement.
- (6) Haustral markings still in evidence. Points at depth of indentations widened.
- (7) No unilateral deformity in any type.
- (8) Bud-like shadows present indicating diverticuli.
- (9) Changing character to the defects.
- (10) Maintenance of flexibility.
- (11) Masses of barium may be seen outside the outline of the colon from ruptured diverticuli.
- (12) Extraluminal. The lesion is always in the wall or in the perisigmoid structures.
- (13) Intestinal obstruction from inflammatory swelling and edema frequently occur. Dilation of the proximal colon not so extensive.
- (14) Spasm of the colon is more likely to occur in inflammatory lesions on account of irritability.

water after the colon has been distended with the barium clysmas. The raising of the sigmoid by the distended bladder brought the lesion into view.

Fisher's method of insufflating the colon with air after the barium has been passed out is a valuable adjunct. Its special value is in polypoid degeneration of the mucous membrane of the colon or any growth which protrudes into the lumen of the gut.

Finally in addition to the above causes for misinterpretation we must not neglect to make a preliminary film before the colon is filled with the barium clysmas, so that extracolonic shadows may not be over-

looked or filling defects caused by intestinal contents excluded. The visualization of the lesion may even disappear after defecation due to sinking of the colon into the pelvis. The reverse of this may also occur, the lesion being most distinctly shown in the roentgenograms made after defecation.

We firmly believe that if the technic as suggested in this communication be carried out with infinite care, proper recognition of the lesion will be possible in the great majority of cases.

A STUDY OF 671 CASES OF PEPTIC ULCER WITH SPECIAL EMPHASIS ON 114 POSTOPERATED CASES

REYNOLD E. CHURCH, M.D.

*Instructor in Surgery at New York Post Graduate Medical School (Columbia University)
Assistant Visiting Surgeon Bellevue Hospital*

and

J. WILLIAM HINTON, M.D.

*Assistant Professor of Surgery at New York Post Graduate Medical School (Columbia University)
Associate Visiting Surgeon, Bellevue Hospital*

During the past six years we have observed 671 cases of peptic ulcer in the Gastro-Enterological Clinic of the Fourth Medical and Surgical Divisions at Bellevue Hospital. These patients have made a total of 11,656 visits, which gives each patient an average of 17 appearances. Of the 671 cases, 507 were unoperated when they came to us for treatment, thus leaving 164 which had previous been subjected to surgical procedure. Our treatment has tended to be conservative and we have submitted each case to a strict medical regime, with frequent examinations before we considered surgery. As a result, we have found it necessary to operate on but 46 of the 507 unoperated cases, or less than 10 per cent, during this period of observation.

These cases have been exposed to the major mishaps that may occur in the course of ulcer treatment, namely, perforation, hemorrhage, and cancerous degeneration. Perforation was found to be a real danger and occurred even after prolonged medical care in patients who were apparently progressing satisfactorily. We were unable to prognosticate this accident by means of prodromal symptoms or x rays which were taken frequently in our clinic. It occurred in 15 cases, or approximately 3 per cent of those we had under observation.

Hemorrhage is always an alarming complication of peptic ulcer. By hemorrhage we refer to the massive type which results in hematemesis or melena of such severity as to incapacitate the patient and necessitate hospitalization due to the presence of shock or secondary anemia. Gastric hemorrhages have at times proved fatal in spite of every effort at supportive measures. Massive hemorrhage is little understood except by those that have had an oppor-

tunity to observe a large group of cases. Therefore, for a more intelligent understanding of the best measures to be employed in the treatment of these cases, one of us¹ was led to make a study of the cases admitted to the hospital for the past twenty-three years. The advisability of dividing them into the following five groups was shown by this study: (1) hemorrhage occurring in patients with a peptic ulcer under competent medical management, (2) hemorrhage in cases, operated on for acute perforation or chronic ulcer, that had never had the catastrophe of hemorrhage until months or years following the operation, (3) hemorrhage occurring in ulcers that had previously been operated on for a hemorrhage and with the patient continuing to have recurring hemorrhages postoperatively, (4) severe hemorrhages that occurred in patients with negative or very short gastric histories and the patient never knowing he had an ulcer until the hemorrhage occurred, (5) patient admitted with hemorrhages and a long history of ulcer symptomatology, but without regulated medical treatment.

The application of this classification in our clinic has been found most helpful. We have been enabled by means of careful histories and observations of the clinical course to place patients in a definite group which has led to a more enlightened management of the complication and to the use of surgical intervention when advisable.

It is in the first group that operation obviously is desirable, for here we have exhausted conservative medical measures. This operation should be delayed until the patient has completely recovered from the acute hemorrhage and has been properly prepared. It is well to remember, how-

ever, that recurrences are prone to occur.

The patients in the fifth group must not be confused with those in the first, for here, although the fifth group give a long history of ulcer symptoms, they have never received adequate medical therapy, and our results show that improvement is obtained quickly in most cases. If they fail to respond, they automatically transfer themselves into the first group and must be treated as such.

Patients in the second and third groups present a most difficult problem. They have previously been subjected to various surgical procedures, often resections. Any new operation must necessarily be only a speculation without very great hopes for success. The only definite indication for operation here is the presence of a bleeding marginal ulcer. Certainly, conservatism combined with a well-regulated, medical régime produces sufficiently encouraging results to offer the most hope.

Hemorrhage as a complication is said to be increasing in the past few years, although with lessened severity. Fifteen cases were observed by us during the six years in our clinic.

The possibility of carcinomatous transformation of a gastric ulcer, a question that has aroused numerous and varied opinions, has not alarmed us and we have treated all cases of gastric ulcer by conservative measures unless the pain was uncontrollable, and then they were referred for operation. We have taken this attitude because no unequivocally proved case of carcinomatous degeneration has ever occurred while under our management. There have been several cases which, at first, were thought to be malignant, but at operation were proved only large indurated ulcers. The following is a typical case:

Male; Polish; tailor; age 48 years; admitted to hospital November 11, 1933. History covered eleven years of symptoms from ulcer. Pain in epigastrium two or three hours after eating was the chief complaint, but was associated with nausea and insomnia. This pain radiated to the left costal margin or directly backward. He had been under medical management in our clinic. There had been a considerable loss of weight prior to admission. A physical examination showed slight tenderness and rigidity over the epigastrium and at the left costal margin. X-ray examination had proved the presence of a gastric ulcer and one taken at admission led to the diagnosis of carcinoma of the stomach. This diagnosis was followed by an exploration. At operation the findings were "a large mass the size of a small orange was felt at the midpoint

of the lesser curvature protruding into the stomach." This was suggestive of a malignancy. A gastro-enterostomy was performed as a preliminary to a resection because the condition of the patient was such he was not considered as a suitable risk for radical surgery at the time. At the second stage, six weeks later, the operator was amazed to find "the extensive reaction noted in the previous operation had largely subsided." Pathological study of the resected stomach showed the ulcer practically healed and no malignancy.

Many of these patients presented themselves to us after periods of medical régime, surgery, or both, with a high percentage of cases failing to get relief from symptoms after each type of treatment. It has not been our purpose to establish dogmatic rules for their treatment, but to emphasize that both medical and surgical methods have their place in different stages of the disease.

In an attempt to determine the type of patient who needs to be operated upon, and the correct time to perform the operation, we have considered as possible determining factors the question of severe pain, obstruction, and hemorrhage. This study led to the use of a long, strict, and varied medical régime on each case regardless of presenting symptoms and x-ray findings. The result has been the belief that ulcers cause very few organic obstructions, and that medication of an antispasmodic nature will, in a majority of cases, suffice to relieve the condition. The cases of moderate hemorrhage as indicated by anemia and tarry stools were treated as ambulatory except those that became sufficiently severe to indicate damage to a large vessel when they were hospitalized to await further developments.

The real indication for operation has been found by us to be severe pain unrelieved by medication or diet. This must be a pain unrelieved by medication or diet. This must be a pain without intervals of relief or periods of remission which is probably caused by the penetration of the ulcer into the pancreas.

It is our belief that pain forms the most important and frequent indication for surgical intervention, and that its cause is probably pancreatic in origin. The desire for a laboratory test to determine the involvement of the pancreatic substance, as shown by changes of pancreatic secretion, led us to carry out the amylose test of Elman² in an attempt to find a means of determining the time for operation. It was

found, however, that the results were not uniform and that examination of the blood taken from dogs with ligated pancreatic ducts failed to show the increases or decreases as expected. A fairly large number of our cases were then selected, some of which were known to have pancreatic damage. In this group our results also failed to show any regularity and uniformity, and we discarded the test as a diagnostic aid.

Since it is always advantageous to evaluate the end results obtained in this type of work, we have selected from the total series our 114 postoperated cases and will place special emphasis on these. We will not include in this discussion 81 cases of perforated ulcer, but will confine ourselves to the postoperated cases of chronic peptic ulcers.

The 114 operations occurred in 103 patients, who visited the clinic 2,224 times for an average period of two years and two months following their operations. This gave us the opportunity of observing them approximately ten times a year over that period. By means of this complete follow-up we are in a position to make valuable deductions, that would otherwise not have been possible by card or letter replies, which we have proved to our own satisfaction are entirely untrustworthy and misleading, as they so often reach the patients in periods of remission and his answer is only for the present. This applies likewise to personal interviews where the patient returns at a given time for an interview and examination.

It is also our belief that this series will prove of considerable value because of the large number of factors we have attempted to determine, so that a type or group could be established in which peptic ulcers are most likely to occur. The following tables and percentages are all taken from the postoperative group.

Inasmuch as men and women of different nationalities are represented, a cross section is offered of the average ulcer individual in his physical conflict. The analysis comprises totals, averages and percentage from 92 males and 9 females, a ratio of ten to one, which bears out the already established conception of prevalence in the male.

Table I presents totals and percentages of the ages of the patients at the time of their operations. This shows the majority suffer from ulcers between the ages of 30

and 50, particularly so in life's period of greatest activity, as indicated by the average age of 37.7 years. The range was from 19 to 65 years. The average length of time symptoms had been present before the operation was found to be 5.9 years, the longest single case being of 25 years.

TABLE I—AGE OF PATIENTS AT OPERATIONS

Age limit	Number	Per centage
10-20	1	1
20-30	17	16
30-40	49	47
40-50	22	21
50-60	11	12
60-70	4	3
Youngest		19 years
Oldest		65 years
Average		37.7 years
Average length of preoperative symptoms		5.9 years

In Table II, the nationalities, or more accurately the birthplaces, are arranged so that a percentage can be computed. This figure would, of course, vary in different localities but certainly does show a high percentage of Irish born and a practical absence of Semetics whose presence would naturally be expected. There was one Negro in this series.

TABLE II—NATIONALITIES OF PATIENTS (BIRTHPLACE)

Nationality	Number	Per centage
American	37	41 plus
Irish	19	21
Russian	10	11 plus
Italian	10	11 plus
Balkan	4	4.4
German	3	3.3
British	3	3.3
Scandinavian	2	2.2
Swiss	1	1
Spanish	1	1

Many claims have been expounded as to the dilatory effects of certain occupations with a tendency towards producing an ulcer. The occupations were listed by us as nearly as possible under headings where similar conditions of exposure, confinement and continuity of duty would be found. They are so listed in Table III. The

TABLE III

Occupation	Number	Per centage
Chauffeurs truckmen automobil me	14	15
Chancians		
Clerks ticket agents cashiers	13	14
Teachers		
Elevator men janitors porters ship-	11	12
ping clerks

Housewives	6	6
Cooks waiters	5	5
Salesmen	5	5
Artists actors bankers	1	3

greatest frequency was observed in chauffeurs and automobile mechanics where 15 per cent occurred.

Duodenal ulcers were found predominant in approximately the same ratio as that calculated by other writers. In Table IV, they are shown with the percentages. Six per cent of the total were marginal ulcers and, in the final calculation, we have corrected for this figure.

TABLE IV.—TYPE OF ULCER

Type	Number	Percentage	Corrected No.	Percentage
Duodenal	92	85	97	88
Gastric	11	10	13	12
Marginal { Duodenal originally 5 } { Gastric originally 2 }	7	6		

A custom usually followed in such a paper is the recording of preoperative symptoms involving the percentages of those suffering from nausea, pain, hematemesis, loss of weight, etc. We have felt, however, that these are too general conclusions and are elicited depending on the amount of pressure exerted on the patient by the examiner. A point of definite importance, one that can easily be obtained by a review of the history is: Why was the patient subjected to surgical interference? A review of our cases is shown in Table V. Certainly uncontrolled pain as alluded to in the earlier part of the paper is shown here to be by all odds the predominating influence.

TABLE V.—WHY WAS THE PATIENT OPERATED?

Symptom	Number	Per cent
Uncontrollable pain	85	79
Obstruction associated with pain	10	9
Bleeding associated with pain	8	8
Obstruction alone	4	3
Obstruction and bleeding	1	1

In 111 cases the operation performed has been described and, although no attempt shall be made to enter into a discussion of the choice of operation, it is imperative to have a knowledge of the technic used in order that later we may evaluate the end results. This information is contained in Table VI.

TABLE VI.—TYPE OF OPERATION

Type	Number	Per cent
Gastro-enterostomy with excision	2	85
pyloroplasty	1	77
enterostomy	2	
Resection including dissociation of old gastro-enterostomy	2	11
Pyloroplasty	7	6.5
Simple excision	5	4.5
Dissociation	3	2

There were 19 cases in this series who suffered from hemorrhages; 11 as a pre-operative complication and 12 postoperatively. There were 7 benefited cases, leaving 4 in which it was recurrent following the operation. If these cases are grouped in the classification mentioned earlier, it will be found that those who failed to be improved by surgery were in the second, third and fourth groups, while those benefited were mostly in the first and fifth. There was one case of a marginal ulcer which was considered cured but which two years later recurred even while under observation. There was one case operated twice with no relief from bleeding.

The question as to what percentage of patients develop gastrojejunal or marginal ulcers following a short-circuiting operation where the jejunum is attached to the stomach as in a gastro-enterostomy or in some forms of stomach resection, is as perplexing to-day as ever, and the controversy between the value of gastro-enterostomies and resections continues. In spite of the claims made, resections of the stomach are followed by marginal ulcers and as our opportunity to study broadens and the time elapsed since the operations lengthens, we are bringing to light more of these cases.

There were 16 cases of marginal ulcers studied in this series. This number occurred following 96 short-circuiting operations, or an instance of 16.7 per cent. These cases were all operated on in the vicinity of New York City, 8 of them being performed at Bellevue Hospital. No one surgeon performed any two operations. Their presence in each case was proved by repeated x-ray examinations or by operation. The recurrence of symptoms in these cases and the presence of the proved marginal ulcer were so closely associated that we can accept them as occurring simultaneously. The average time that elapsed between operation and recurrence of symptoms with a marginal ulcer was found to be four years. The earliest case was one of only three months' standing; the longest occurred after twelve years of freedom from symptoms. We have reported these cases of marginal ulcer occurring with gastro-enterostomies in great detail elsewhere.³ The lessons learned and the percentage found proved interesting. There are present in this series 85 postoperated cases of gastro-enterostomies in which 14 marginal ulcers later occurred. This gives a percentage figure of 16.4 per cent. There

are also 11 operations with stomach resection in which 2 cases later shows marginal ulcers. This gives a figure of 182 per cent.

Aside from the computation of percentages, a study of these cases has shown us that marginal ulcers follow to a great extent the same course as a peptic ulcer. Pain with periodicity and intervals with freedom of symptoms for weeks or months occur; also, that these cases respond to medical treatment in much the same manner as any peptic ulcer. We have subjected each case to an active medical régime and have considered operation only when we have been unable to relieve pain. This symptom when persistent is, in our opinion, the result of the marginal ulcer perforating into some adjacent viscus, and the pancreas and transverse colon are the organs most usually involved.

We have found that repeated x-ray examinations may be negative and the marginal ulcer disclosed only at operation, also that a marginal ulcer may not show in every examination made.

There were 106 cases in which the results were interpreted. These end results we have tabulated under three categories: (1) *Cured*. Under this heading we have placed all cases which have been symptom-free since their operation, perform their customary duties, eat regular foods and resume their normal contributions to society. There are 39 patients (37 per cent of the series) found here. This included those following 33 gastro enterostomies, 4 resections, 1 pyloroplasty and 1 simple excision. (2) *Benefited*. In this group are included those individuals who, although still suffering from mild digestive disturbances, resume their former activities and again take part in the competitive field. They must always exercise dietary restrictions and supplement this with occasional alkaline medication. In this group we have 13 others, or 12.2 per cent. They followed ten gastro enterostomies, 2 pyloroplasties and 1 dissociation. (3) *Unimproved*. Under this category we have placed those cases that received no relief, were worse, have died from an ulcer complication, or have had a recurrence of symptoms with original intensity. There are 55 cases, or 51 per cent, that we place in this group. Of these 16 have developed marginal ulcers. Three have died, one four years after operation from an unknown ulcer com-

plication, probably hemorrhage, a second, two years after operation from a gastric hemorrhage, and the other, one year after his first operation when a stomach resection was being performed for a marginal ulcer that had developed. These followed gastro-enterostomies. Thirty-six cases show either no relief or a recurrence of symptoms. These followed 25 gastro enterostomies, 4 pyloroplasties, 4 excision of ulcers, 2 resections, and 1 dissociation of old gastro-enterostomies. There were 11 cases in which no relief whatever was obtained and symptoms continued following the operative procedure. Twelve cases had a recurrence of symptoms under one year. These cases were never materially benefited and must be classed as immediate operative failures.

The remaining 13 cases received relief from their symptoms for varying periods following operation. However, since recurrence was in each instance as severe as originally and was incapacitating, we have classed them as unimproved. There were 6 of these cases in which the recurrence was over five years, and one occurred twelve years after operation.

COMMENT

An individual with a peptic ulcer differs from the ordinary patient in that he is a wanderer going from office to office and clinic to clinic. This is undoubtedly the result of his search for relief from an illness whose cause he so little understands. This wandering or "shopping" is also caused by the fact that "failures do not return." They always hope that the next physician or hospital will provide them with a cure. They present the type of case

that does not respond to a follow-up request and who reports himself as well when, in truth, he may have just recovered from a severe upset and even then be under another doctor's treatment. Thus, the periodicity of this disease plus the failure of the patient to interpret properly symptoms when asked are the reasons we believe letter follow-ups to be of no value.

When one considers that some of these patients have had symptoms for twenty-five years, each remission must fill them with hope or they would be unable to carry on.

In a study of these cases where we have an average combined history and observation period of four years postoperatively with most of them over five years and one covering twenty-two years, we have found so many recurrences coming on long after the case has been classified as cured to give us the belief that all cases should be followed for at least ten years. Many ulcers that would have healed and remained so are never benefited because dietary régime was not continued after the operation. This is one of the most valuable parts the surgeon plays. He should see that the patient does not injure himself by dietary indiscretions.

We feel this direction should continue as long as the period of observation.

Patients come to a physician for relief and cure and the treatment that is to follow depends entirely on their condition and clinical reactions. There is a time when surgery is indicated. Pain unrelieved by medication is the primary indication for surgical intervention. Once such a procedure has been determined, the type of operation should be a matter of surgical judgment at operation.

Our study shows that such surgical procedures offer the possibilities of cures, benefited, and unsatisfactory cases. The ratio of these may not be similar to that of other observers; but surely our figures do not present a very optimistic outlook for the treatment of ulcer sufferers by present methods. Perhaps what we need is an enlarged surgical armamentarium but most likely it is the need of knowing what causes an ulcer.

A DOCTOR'S FEE IN THE LOUISIANA BAYOUS

When Dr. Payne came home, his neighbors were getting ready to organize a rescue party. He had been away two days, on a remote island across bays and canals and bayous, to bring another little "Injun" into the world. He had had no sleep, for he was too busy fighting mosquitoes, and nothing to eat or drink but coffee, for that had been boiled and was probably harmless. His home is in Napoleonville, La., and Dr. Peel M. Payne tells about it in the Medical Record. "After the little Injun arrived," he says, "the question was asked me 'How much do we owe you?' I told them whatever they thought the 'Bon Dieu' would want them to give me. They

looked at each other, then at me, and said 'We owe you the life of the woman and child; name your price.' I told them five cents for every mosquito bite. The old man asked me if I wanted to own the island.

"I finally told him 'Give me 100 rat skins (\$1.00 each). 'Je suis un homme pauvre, tres pauvre,' he said, 'but you have treated us as though we were rich; you have rendered us "un grand service" and we shall do as you say.' I told him he could keep the 100 rat skins, give me \$75.00 and get me back to Montegut. That was satisfactory to everybody. Muskrats are known as 'Louisiana Gold' but on the whole I preferred dollars."

ANTI-INFLUENZA SERUM

An anti-influenza serum has been produced in a horse by the three British scientists who last year isolated the influenza virus, according to a Science Service dispatch from London. The same scientists have found a way of systematically using mice, the most widely available of all animals used in medical research, for intensive experiments in the long-continued war against influenza.

This dual announcement is made in the current issue of *The Lancet*, medical journal pub-

lished in London. The three scientists are Drs. C. H. Andrewes, P. P. Laidlaw and Wilson Smith, all of whom are working at the National Institute for Medical Research Farm Laboratories, at Mill Hill, a suburb of London.

Details concerning the horse serum, the doctors announce, will be published later. For the moment medical men and laymen alike have to wait as patiently as possible for the promised full account of what may prove to be one of the most important medical advances for many years.

THE SCHILLING HEMOGRAM: ITS VALUE TO THE SURGEON

ARTHUR M. DICKINSON, M.D.

Albany

That the usual total and differential leukocyte counts are of considerable value to the surgeon cannot be denied. We have all placed considerable dependency upon them and will probably continue to do so. On the other hand, too frequently we have encountered those instances in which the conventional counts were misleading or difficult to correlate with the clinical findings. Confronted with this situation, older surgeons have disregarded the blood count, depending upon clinical judgment entirely; younger surgeons with more dependence upon laboratory findings have been led astray. Such difficulties with the conventional type of count can in a large measure be eliminated by the use of the Schilling hemogram.

A thorough understanding of the origin and development of the various kinds of leukocytes and the fundamental reaction of the blood in the presence of sepsis are basic to interpretation of any blood count. All granular leukocytes, neutrophiles, basophiles, and eosinophiles have their origin in the bone marrow; lymphocytes originate in the lymphatic tissue; mononuclear and transitional cells may originate in the reticulo-endothelial system, but this remains to be fully accepted. We, however, are chiefly concerned with the granular leukocytes (granulocytes), and especially with the neutrophiles. The parent cell of the granular leukocytes is the myelocyte which develops from the myeloblast and is normally found in bone marrow only. The maturation of the myelocyte to the adult neutrophile is an important factor in the Schilling count.

The Schilling hemogram is an outgrowth of the Arneth count which is perhaps better known under the title of "shift to the left." It had been recognized for a long time that infection brought about certain definite changes in the leukocytes, especially the neutrophiles. It had also been observed that in acute infections, younger or immature forms of neutrophiles appeared in the circulating blood in increasing num-

bers. Making use of this knowledge, Arneth studied the blood of infected individuals and divided the neutrophiles into five groups depending upon the number of lobules of their nuclei. These groups were further subdivided until there was a total of 21. By counting the number of each different group, certain definite and helpful information was obtained. The term "shift to the left" was used to designate those counts in which there was an increase of the immature forms of neutrophiles at the expense of the more mature ones. The Arneth count was and still is very valuable, but it is time consuming and requires an expert technician.

To meet these objections, Schilling modified the Arneth count by reducing the different groups of neutrophiles to 4 instead of 21. These groups will be briefly described. The first of these was the myelocyte which never appears in the circulating blood of a normal individual; it has a kidney- or oval-shaped nucleus, often containing nucleoli; the protoplasm contains coarse neutrophilic granules. The next group in order of maturity is the so-called juvenile cell which normally does not appear in the blood stream; this cell has a sausage- or bean-shaped nucleus with nucleoli. The next group is represented by the stab or staff cell; in this cell the nucleus is narrow or band-like and contains no nucleoli; under normal conditions 2 to 5 per cent of these cells appear in the blood stream. The final group contains the adult or segmented form of neutrophile; its nucleus is segmented and the segments are usually connected by threads of nuclear tissue; these cells make up about 63 per cent of the normal white cell count. Furthermore, under the heading of monocytes, Schilling includes both large mononuclear and transitional cells, the separate counting of which is probably of little value. So then, a Schilling hemogram records the percentage of basophiles, eosinophiles, the various groups of neutrophiles, lymphocytes, and monocytes. If the recording is

done in the above order and a line drawn between the stab and segmented cell counts, we are in a position to visualize any "shift to the left."

What happens to the leukocytes in the presence of infection? In the primary stage, the mature neutrophils (segmented forms) are the first line of defense. As these are destroyed, fresh neutrophils are required to replace them. Often in progressing infection, nature is unable to mature the neutrophils rapidly enough and so stab cells commence to appear in the blood in increasing numbers. Many of these show evidence of their own immaturity by degenerative changes and vacuolization. Concurrent with these changes, the

differential diagnoses between urgent surgical conditions and those which require more conservative treatment. It enables us to tell which way the tide of battle is turning. It will often foretell the development of serious complications or predict a fatal outcome hours in advance of the clinical evidence. It enables us to read between the lines, as it were, when we get a normal or subnormal total leukocyte count in the presence of clinical evidence of infection.

To illustrate the value of the Schilling hemogram, the author presents a limited number of actual counts done on patients at the Memorial Hospital during the past year.

TABLE I

Count No.	Total WBC	Per cent Polys.	Bas.	Eos.	Myel.	Juv.	Stab.	Seg.	Lymph.	Mon.	Description
N	7,500	67	1	3	0	0	4	63	23	6	So-called normal

9	9,440	74	1	2	0	4	12	58	21	2	Subacute P. I. D.
10	12,280	86	0	0	0	10	57	19	13	1	Ac. P. I. D.; small abscess
11	10,830	83	0	0	0	2	26	55	15	2	Septic abort.; thrombophlebitis
12	6,640	72	2	1	0	7	35	30	24	0	Septic abortion; septicemia
13	7,880	64	0	4	2	3	18	41	32	0	Same; 8 days later
14	6,880	73	1	2	0	0	16	57	24	0	Same; day before discharge
15	7,300	86	1	2	2	2	12	69	11	0	Gallstone colic

total leukocyte count is usually on the rise, although in many instances, its curve does not parallel that of the neutrophilic increase. Further advance of the infection results in the appearance of younger neutrophils yet, the juvenile form; finally in the severe type of infection, the myelocytes themselves appear in the blood stream. During this period of progressing infection, gradual disappearance of the eosinophiles will be noted; along with these changes there will be a decrease in the lymphocyte and monocyte counts, also. Such are the changes accompanying progressing infection. With resolution and recovery from the infection, the reverse of these changes occurs until the normal blood picture reappears.

From this theoretical consideration, we now turn to the practical application of the Schilling hemogram. It is of definite diagnostic value. It frequently makes possible

On the first line of Table I can be seen the so-called normal hemogram. Note the double line to the right and left; between these lines are placed all the neutrophils. Also note the single line marking off the column of segmented neutrophils. Increase of the percentages of the immature forms of neutrophils thus constitutes a "shift to the left" in relation to this column. The percentage of polymorphonuclear neutrophils has been included with each hemogram so that comparison between the conventional and Schilling types of count may be readily made.

Count 1 is from a patient admitted with a temperature of 100° F. and pulse of 110 and a diagnosis of acute appendicitis; operation disclosed a gangrenous appendix with no peritoneal involvement. Here the total white blood count and the differential count of the conventional type seems to fit the clinical picture. Note, however, the

positive but slight "shift to the left" in the hemogram.

Count 2 is from a case of acute gangrenous appendicitis with beginning peritoneal involvement; there was some free pus present. The admission temperature was 102° F. and the pulse 130; the duration of symptoms was 24 hours. Note the low total white count, the relatively high percentage of neutrophils, and the more marked "shift to the left," also the absence of eosinophiles and the decrease in lymphocytes and monocytes.

Count 3. This patient was admitted with a temperature of 102° F. and pulse of 120, with symptoms of appendicitis and spreading peritonitis; the onset was less than 16 hours before admission. Immediate operation disclosed a perforated gangrenous appendicitis with general peritonitis; the latter was confirmed by subsequent post-mortem. There is little of note in this count except the definite increase in neutrophils and the moderate "shift to the left."

Count 4 is from the same patient three days later. Note the low total white count, always of bad import; there is, however, a high percentage of neutrophils. The juvenile forms have increased markedly at the expense of the segmented forms. At this time the clinical condition of the patient was fair. The abdomen was soft; there was no vomiting; gas was being passed by rectum; the temperature and pulse were not at all bad. The hemogram was in marked contrast to the clinical picture.

Count 5 is from the same patient two days after the preceding count and about 12 hours before death. Note the finding of 8 myelocytes and the marked increase of juvenile forms. At this time the patient's temperature was 105° F. and the pulse 140.

Count 6 is interesting in retrospect. This patient was admitted with a temperature of 98.6° F. and pulse of 60; there was a history of an attack of severe upper abdominal pain of 24 hours duration following months of indigestion. The abdomen was tense and retracted; there was no vomiting. The question was "is there a perforated ulcer?" No operation was done. Subsequent study revealed a definite duodenal ulcer with adhesions, so apparently

the acute episode was a minor perforation. The hemogram shows a definite "shift to the left."

Count 7 is from a patient admitted to hospital three days after perforation of a peptic ulcer. The admission temperature was 99.4° F. and the pulse 130. The abdomen was distended and board-like. Operation was not done. The patient expired 8 hours after admission. Post-mortem confirmed the clinical diagnosis. Note the low total white count and also the low percentage of neutrophils which might have been misleading. The hemogram, however, vividly portrayed exhaustion of defense.

Count 8. This patient had a ruptured tubal pregnancy of 24 hours duration with a moderate amount of free blood in the peritoneal cavity. Here we see a mild but definite "shift to the left."

Count 9. This patient had a mild pelvic inflammatory disease and was not operated upon. Note the mild reaction.

Count 10. This patient had a real acute pelvic inflammatory disease with later abscess formation. She was admitted with a temperature of 103° F. and pulse of 110. Note the marked increase of juvenile and stab forms at the expense of the segmented forms.

Count 11. This patient had a septic abortion. She was admitted with the usual physical signs and a temperature of 100° F. Conservative treatment was followed until the process had apparently quieted down. Then the uterus was gently emptied, following which the temperature rose to 103° F. The hemogram was done on the same day. Note the mild "shift to the left." Three weeks later the patient was discharged well.

Count 12. This patient developed infection following curettage for an incomplete abortion. She had a thrombophlebitis of the pelvic veins with a clinical septicemia. Note the swing to the left in her hemogram.

Count 13 is from the same patient eight days later. Note the persisting low total white count, the falling neutrophils and the appearance of myelocytes.

Count 14 is also from the same patient, eight days after the above and four days before discharge from hospital. Note the reaction toward recovery. The myelocytes

and juvenile types have entirely disappeared and the eosinophiles have reappeared.

Count 15. This is from a patient who entered the hospital with a normal temperature and increased pulse complaining of pain in the right side of the abdomen with nausea and vomiting. There was some tenderness and spasm of the right rectus. Conservative treatment was followed and subsequent study revealed the condition to be gallstones. Note the moderate shift in this hemogram.

CONCLUSIONS

The Schilling hemogram offers the surgeon more assistance in certain forms of sepsis than the conventional total and differential white blood counts.

It is very helpful in differentiating acute surgical conditions from those conditions requiring conservative treatment.

It is very valuable as a prognostic aid, often revealing evidence of the onset of serious complications several hours before any clinical change is noted.

302 STATE STREET

DISEASE CARRIED BY AIRPLANES

Most of the important countries of the world have signed the International Sanitary Convention for Aerial Navigation, which aims to minimize the conveyance of disease from country to country by air. As told by the London correspondent of the A. M. A. Journal, each country undertakes to provide at its aerodromes a sanitary organization adapted to the current needs of prophylaxis.

The sanitary aerodrome will have (1) equipment for taking and dispatching suspected material for examination in a laboratory, if such examination cannot be made on the spot; (2) facilities for the isolation and care of the sick, for the isolation of contacts separately from the sick, and for the carrying out of disinfection and deratization.

In the journey log of the aircraft the following must be entered: 1. Any facts relevant to public health which have arisen in the course of the voyage. 2. Any sanitary measures undergone by the aircraft before departure or at places of call, in application of the present convention. 3. Information concerning the appearance in the country of departure of the following infectious diseases: plague, cholera, yellow fever, typhus and smallpox.

If any of these diseases appear in a noninfected country, the aerodrome authorities shall enter the information in the journey log of any craft leaving it during a period of fifteen days from the receipt of the information. The medical officer of the aerodrome has the right of sanitary inspection of the passengers and crew, and on his advice the embarkation of persons with symptoms of infectious diseases may be prohibited. Aircraft in flight are forbidden to let fall matter capable of causing an outbreak of infectious disease.

Plague, cholera, yellow fever, typhus and smallpox are subject to special measures. For purposes of the convention the period of incubation of plague is reckoned as six days, of cholera five days, of yellow fever six days, of typhus twelve

days, and of smallpox fourteen days. The measures to be adopted on the departure of an aircraft from a local area infected by plague, cholera, typhus or smallpox are (1) thorough cleansing of the aircraft, (2) medical inspection of passengers and crew, (3) exclusion of any person showing symptoms of these diseases as well as of persons in such close relation with the sick as to be liable to transmit these diseases, (4) inspection of personal effects, which shall be accepted only if in reasonable state of cleanliness, (5) in case of plague deratization, if there is any reason to suspect the presence of rats on board.

On arrival from such infected areas the aircraft may be required to land at a prescribed sanitary or authorized aerodrome and the movements of the passengers and crew may be restricted. If there is on board a recognized or suspected case of plague the following measures are applicable: (1) immediate disembarkation of the sick, (2) surveillance of contacts and suspects for a period not exceeding six days, (3) disinfection and disinsectization of personal effects, and (4) deratization. For a case of cholera the measures are similar except that the period of surveillance is five days and the drinking water may be disinfected and emptied. For typhus the measures are similar except for delousing and surveillance for twelve days after this. For smallpox the special measures are vaccination and surveillance for a period not exceeding fourteen days of those on board. In regions in which yellow fever has occurred or is endemic aerodromes must be at an adequate distance from the nearest inhabited center, provided with a water supply protected against mosquitoes and with mosquito-proof dwellings for the aircraft crews and for the accommodation of passengers. The aircraft and cargo must be inspected to see that they do not contain mosquitoes and, if necessary, disinfected. Passengers and crew may be put under surveillance for six days from exposure to infection.

EDITORIALS

Occupational Diseases of the Physician

This vital topic was the subject of a recent scholarly address in London by Dr. Sir Humphry Rolleston, an eminent English physician and baronet. It coincides with the publication in this country of an informing booklet on "Death Rates by Occupations," which reveals among other things the causes that snap the vital thread of the medical man here. We all remember the story of the man who said: "I wish I knew where I was going to die." "What do you want to know that for?" asked his friend. "Sure," he replied, "then I would never go near that place!"

In a similar way, if the doctor knows what ailments are most likely to attack him, he can guard against them, and may be able to add years to the span of his usefulness to his fellow-men. "Physician, heal thyself," is the familiar quotation from St. Luke, but Sir Humphry remarked that the correct translation is "treat thyself," and perhaps we may modify it to "care for thyself," and may urge the doctor to watch for the diseases that beset his profession, and at least to use the

common sense in taking care of himself that he enjoins on his patients and too often disregards in his own case with a reckless courage that is as unwise as it is admirable.

The death-rate for American physicians and surgeons is gravely higher than the general figure for all the workers covered in the study of "Death Rates by Occupations." The medical death rate is 10.69 per thousand, as against 8.70 for all "gainfully occupied males." The study covers ten states, including New York. An even worse contrast appears when we see that the rate for all professional men (including the doctors) is only 7.00, bringing the medical rate more than 50 per cent above the general professional level. Those who revel in statistics may be interested to compare the doctors' rate of 10.69 with the rate of 7.89 for lawyers and judges; 10.33 for clergymen; 2.69 for college presidents and professors; 7.68 for dentists, and 4.88 for trained nurses. The low average age of the nurses may account for their low rate, but what is the reason for the very low mortality of the college presidents and professors? There is something to look into.

Two diseases generally thought to be frequent among active practitioners, says Sir Humphry Rolleston, are angina pectoris and duodenal ulcer, and he observes that worry may well play a part in both. Osler spoke of angina as *morbus medicorum*. At any rate, its incidence among medical men has been considerable.

Surgery has not only its physical strain but its risk of infection, streptococcal, pneumococcal, and syphilitic. An investigation in 1926 at the Manchester Royal Infirmary showed that in the first quarter of the century the death rate of the surgeons was nearly five times that of their medical colleagues. The post-mortem rooms, too, have killed, crippled, or damaged many pathologists investigating the causes of the death of others.

Then there are the bacteriologists, who are exposed to infection in dealing with bacterial cultures. Tularemia, while actu-

ally a rare disease, has attacked laboratory workers both here and in England. Tuberculosis may be started in a laboratory by inhalation. Other diseases that have taken the lives of bacteriologists are enteric fever, typhus, Rocky Mountain fever, yellow fever, plague, glanders, undulant fever and African fever.

Radiologists are affected by various pathological conditions caused by irradiations, chief of which, probably, is radiologists cancer. Sir Humphry recalls that in 1911 Krause referred to the death of 54 radiologists from malignant disease; in 1922 Ledoux-Lebard estimated that 100 radiologists had died from this cause, and in 1934 Colwell and Russ have found that the total is now more than double this figure. A curious fact is that it is the x-ray workers who suffer from malignant disease, while the cases of carcinoma due to radium are remarkably few. The radium workers, on the other hand, tend to suffer from anemia, while the x-ray workers are free from it. It seems that the blood changes produced by radium are of the same character as those described in x-ray workers, but the gamma rays of radium have a much greater tendency than x-rays to produce anemia.

Why do physicians tend to become victims of their own specialty? Some believe that auto-suggestion is responsible. It is not uncommon for a medical man to manifest the symptoms of the disease in which he is especially interested, and a number of them have eventually suffered from organic diseases of the system of the body on which they had previously concentrated their attention.

Turning now to the list of diseases that carry off the physicians and surgeons, as recorded in "Death Rates by Occupations," we are not surprised to find diseases of the heart, by far the most important—looming larger, in fact, than any other three causes put together. Next in importance are cancer and other malignant tumors, followed closely by nephritis, cerebral hemorrhage and softening of the brain, and pneumonia. Then come tuberculosis, cirrhosis of the liver, and appendi-

citis. Far down the list is duodenal ulcer, which Sir Humphry mentioned as frequent among British physicians. Glancing along the figures, we find that the doctors appear to suffer more from heart-trouble than most other workers, and much less than others from tuberculosis. In the cancer column they stand a little higher than the average and in pneumonia and appendicitis are about par.

In short, the doctor is human, and cannot expend his vitality recklessly, day and night, without paying for it himself. That tragic figure of deaths from diseases of the heart tells the story—overwork, overstrain, worry, lack of sleep—there it is, written plain. That is an "occupational disease" that will never cease as long as the doctor breathes the spirit of service and sacrifice that has marked the profession from its beginning and will continue to its end.

Yellow Fever Not Conquered Yet

The popular idea that yellow fever has been vanquished is a mistake, it seems. We have been lulled into what is perhaps a false sense of security by the fact that the terrible yellow-fever epidemics which used to decimate the populations of New Orleans, Havana, Panama, and other cities around the Gulf and the Caribbean, are no more.

It appears that instead of being wiped out of existence, yellow fever has only retreated to the interior of South America and to the half-civilized regions of West Africa, ready to appear and take its toll again if ever vigilance is relaxed. As far as known, these regions are the main ones now affected, and if they can be cleared up then there will be little or no more virus for the *stegomyia* mosquito, the *Aedes aegypti*, to carry from the sick to the well, and so keep the dread chain of infection going.

The difficulty in tracing our old enemy commonly known as Yellow Jack has been partly due to the fact that the natives in Africa and South America who had it merely knew they were sick, without know-

ing or caring particularly what the name of their misery might be. In one locality everyone had supposed it was the grippé. Again, it can continue for years in a mild form in rural regions without attracting any special notice.

This explains why yellow fever has failed to disappear from Brazil, in spite of determined campaigns in the cities, and why it reappeared in Colombia a few years ago with no signs to show where it came from. It has appeared too, in spots where no *Stegomyia* mosquitoes were found, showing that other carriers may also be guilty.

The ingenuity of the medical workers who have been investigating this matter is worth our notice. The problem was to discover regions where yellow fever prevailed, and it might happen that there was not a single case within a hundred miles of the spot under scrutiny at the moment. But perhaps there had been an epidemic of some sort a few years previous. Was it yellow fever? No one knew. But a test was devised to find out. If it was, then it had left its mark in the blood of the patient, for the blood of one who recovers protects him from yellow fever for the rest of his life. If, then, blood serum from this person is injected, together with yellow fever virus into a healthy white mouse, the mouse will be protected from the virus and will survive. In other words, if the mouse survives, then the person under investigation has at some time had yellow fever. If the mouse dies, he has not.

Many thousands of blood specimens from many parts of the world have been tested in New York, in Nigeria, Africa, and in Bahia, Brazil, and have revealed the fact that yellow fever is still lurking in West Africa and in the interior of South America. Throughout the world indeed, the areas where yellow fever has been found are much larger than would have been expected from known experiences with the disease. In the South American investigations another test has also proved useful. Microscopic examination of liver tissue of persons dying after brief febrile illness is a widely used method of discovering fatal cases of the disease. The liver

examinations show where people are dying of yellow fever. In one village in Brazil where yellow fever was suspected not a specimen of the *Aedes aegypti* mosquito was found, but the very first liver specimen betrayed evidence of yellow fever.

These vastly interesting and important investigations are being carried on by the giant efforts of the Rockefeller Foundation and the various governments administering the territory involved. The aim of the Foundation is merely to uncover the conditions, point out the way to cure them, and then hand over the task to the national authorities, who have the necessary police and military power to carry out the health measures required. Informing articles telling in more detail about the work have been published in London, Paris, and various South American cities. American readers will find excellent reports in *The American Journal of Hygiene* (Baltimore) in its issue for November, 1933 and May, 1934. The facts given here are taken from the Foundation's Annual Report, just published.

Incidentally, these yellow-fever investigations developed a method of vaccination against yellow fever by the injection of human immune serum and living yellow fever virus as fixed for mice. It was begun in 1931 and the number of persons vaccinated in the laboratories of the Rockefeller Foundation has now reached 56, principally members of the staff, government officials, missionaries, scientists, and educators going to infected lands. It has been successful. So far as known, no one vaccinated has contracted the disease, although accidental infections in the laboratory and field had previously been frequent and seemingly unavoidable.

This remarkable campaign which is pursuing yellow fever to its most remote and secret hiding places affords a thrilling chapter in the history of our war on disease. But for real thoroughness, we must turn to the *Aedes (Stegomyia) aegypti*, which has been carefully watched at work and has been found to inject at least 100 infective doses of the yellow fever virus during a single active feeding. That's efficiency.

of Interest to the Profession

THE STATE JOURNAL—PRESIDENTIAL ADDRESS

ARTHUR J. BEDELL, M.D.,
Albany

Delivered before the Fifth District Branch Meeting at Syracuse, October 2, 1934

The first issue of the Journal of the New York State Medical Association under the direction of a Publication Committee appeared on January 1, 1901. It was attractive in appearance and neatly printed. Pennsylvania and Illinois had been publishing their journals for a few years, so that ours was the third in the United States. The price was \$1.00 per year. The policy of the Association was to avoid unnecessary controversy but communications from members were solicited.

In March, 1906, James Peter Warbasse became the editor, and the Journal was given a gorgeous yellow cover. To the younger members it might be well to explain that for several years there was the Medical Society of the State of New York and the New York State Medical Association but that in 1906 the organizations were merged under the name of the Medical Society of the State of New York.

At the end of three years Algernon Thomas Bristow took charge and removed the distinctive cover. He served for five years when John Cowell MacEvitt assumed the editorship and presented the Journal in an attractive gray cover.

In 1922 Frederic E. Sondern was the editor with E. Livingston Hunt and Joshua Van Cott associates. It was at this time that as a member of the Publications Committee I became especially interested in the conduct of the publication. In 1923 Nathan B. Van Etten became the acting editor and Orrin S. Wightman and Albert Warren Ferris his associates.

In 1924 Frank Overton was appointed the Executive Editor, while in 1926 Orrin Sage Wightman was elected the editor. He served with fidelity, with interest and marked business ability until the beginning of 1934 when under the press of other affairs he resigned.

Since January 1, 1934, the Journal, which was previously published directly by the Society has been under the control of a Journal Management Committee. Mr. Thomas R. Gardiner then took charge of the business management. There has been no editor or

associate since that time. The Journal is sent to every member of the State Society. According to the present financial arrangement fifty cents is given the business manager for every member and forty cents is allocated to the Journal Management Committee.

I have sketched the life of the Journal so as to interest you in its future. All of the papers read before the Annual Meeting become the property of the State Society and may be published in the Journal. Most of the District Meeting addresses, but only a few of the communications presented before County Societies reach the Journal readers. This is unfortunate. With your help the Journal of the State Society will steadily improve and become one of the dominant voices in organized medicine. This will not be accomplished until we have a full-time editor trained in medicine, versed in the economic upsets of the day and heartily in accord with the State Society management. The editor must have a rare sense of discrimination, a penchant for concise interpretation of all that is going on in the world of medicine. He must be fearless and a man capable of placing before us the actual conditions under which the physician practices and why we object to the encroachments of foundations and state agents. He must have the skill to ferret out and expose the pernicious influences that are attempting to destroy unified, organized medicine. He must have the forcefulness of the erudite Fishbein and the devotion of Whalen whose editorials and comments are of the greatest value to all who appreciate the faithful discharge of a mighty obligation.

The 1934 volume has a distinctive cover and comes to you in an envelope so that you can easily and conveniently read it. The typography of the present issue is far from ideal.

The Journal Management Committee is anxious to receive your criticisms and your help. Under the latter heading it wishes your medical papers. It should be the duty of the Secretary of every County Society to send a concise report of every meeting.

When possible the papers read before his meetings should be sent to the Journal Management Committee so that, if possible, they can appear in the Journal. There should be columns devoted to the actual economic problems of the day. By this I do not mean the theory and practice of economics as it applies to the universe.

The Secretary of The State Society should have an information column in every issue of the Journal. The Executive Officer should have a space devoted to the pluses of our organization under his direct management. The standing committees should so report on their activities that as soon as their findings have been acted upon and officially adopted by the House of Delegates, Council, or Executive Committee, they can be published so that every member of the State will know the stand taken by the elected officers. There is a definite provision in our By Laws which says

No findings of a Committee shall be binding upon the Medical Society of the State of New York until ratified by the House of Delegates or by a two thirds vote of the Council sitting ad interim."

Had this mandatory rule been followed we would not have the irritation and constant need of denying that the State Society has a State Fee Bill, nor would we at this time

have to disclaim fatherhood of the confiscatory TLRA rates. I or the State Society as such, has never empowered a Committee to adopt any fee schedule.

The reports from the Medico legal department should be explained and where a verdict is rendered the citation should be published. There should be news columns devoted to the outstanding achievements of our members: correspondence and inquiries, communications, etc.

We should return to the plan adopted in the first journals and have a record of deaths. When the men who have served our Society with unselfishness and devotion pass to their reward, a praise should be taken to honor their memory.

The book reviews should be continued just as long as competent reviewers are in charge of the work.

The advertisements must meet the highest ethical standards. The Journal must appear in an attractive readable form.

To discard some of the old and institute the new takes time and money but both of these can be easily secured through our State Society. But what we need most is your individual cooperation as a potential author and as a constant reader. You should learn to use your State Journal.

344 STATE STREET

"HOW TO KILL A MEDICAL SOCIETY

Some of our medical exchanges are reprinting 'for the good of the order' the advice that appeared originally in the *Illinois Medical Journal* on "How to Kill a Medical Society". It is worth remembering

1 Don't come to the meetings. If you do come, come late.

2 If the weather doesn't suit you, don't think of coming.

3 If you do attend a meeting, find fault with the work of the officers and other members.

4 Never accept office, as it is easier to criticize than to do things. Nevertheless get sore if you are not appointed to a commit

tee, but if you are, do not attend the committee meetings.

5 If asked by the chairman to give your opinion regarding some important matter, tell him you have nothing to say.

6 After the meeting tell everyone how things ought to be done.

7 Do nothing more than is absolutely necessary but when other members roll up their sleeves and willingly and unselfishly use their ability to help matters along, howl that the organization is being run by a clique.

8 Hold back your dues as long as possible, or don't pay at all.

9 Don't bother about getting new members, let George do it.

MEDICAL BROADCASTS

Scheduled under the auspices of the Medical Information Bureau of the New York Academy of Medicine and the Medical Society of the County of New York from Station WABC, Columbia Broadcasting System

Thursday, December 20, at 11:15 a.m., 15 minutes

Subject: Modern Trends in the Treatment of Tuberculosis

Speaker: Dr. Herbert R. Edwards, Director of the Bureau of Tuberculosis, New York City Department of Health

TWO DANGEROUS DRUGS

A warning is sent out by the Federal Food and Drug Administration in view of the widespread use of two dangerous drugs—one which destroys the liver and the other which kills the white corpuscles of the blood. These drugs are cinchophen and amidopyrine. Cinchophen, a chemical anodyne and sedative, is sometimes used by sufferers from neuralgia, rheumatic pains, neuritis and similar conditions. Amidopyrine is frequently found in headache remedies and other pain killers.

"Current medical literature contains many reports which clearly indicate that these drugs are dangerous to health and life," says W. G. Campbell, Chief of the Food and Drug Administration. "The gradual development of serious poisoning from the use of these drugs is often so insidious that the danger is not recognized by the user. Cinchophen causes a degeneration of the liver cells. Amidopyrine may cause a reduction in the number of white blood cells, a condition called agranulocytosis."

In issuing the warning Mr. Campbell made it plain that he was not implying that all headache and rheumatism remedies contained these dangerous drugs. But the fact that some of them do is sufficient reason for the public to be careful. Several manufacturers declare on their labels the presence of these drugs in their medicines, but others

do not. There is no provision in the Food and Drugs Act to compel manufacturers to declare either of these drugs.

The Federal Food and Drugs Act requires manufacturers to declare upon the labels of their products the presence of several narcotic drugs. When the law was passed cinchophen was unknown and the dangerous effects of amidopyrine had not been recognized. For these reasons these drugs were not included in the list.

Under present conditions buyers should observe two precautions. First, read the label and look for statements of the presence of these drugs. If they are not declared and there is any doubt ask the druggist or write to the Food and Drug Administration in Washington and ask for the facts.

In connection with this, the following excerpt of a letter from Parke, Davis & Company, may be of interest:

"It is our opinion that amidopyrine is a very useful drug and that its intelligent therapeutic application should not be abandoned because of the fact that under certain conditions it is capable of doing harm. The same thing is true of many other medicinal substances. If we were to eliminate from the *Materia Medica* all drugs which might, under certain conditions, be harmful there would not be very much left in the way of potent medication."

SETBACKS FOR CHIROPRACTORS AND NATUROPATHS

Stinging defeats were administered to efforts of chiropractic and naturopathy to aggrandize those cults on election day in Arizona, California, and Oregon. Measures tending to give them more and better standing and authority came up for decision of the voters in all three states, we are told in the *A. M. A. Journal*.

Through the effective work of the state medical associations of Arizona, California and Oregon, and with the aid of many public

spirited citizens both individually and in organizations, the people were kept informed as to the dangers threatened by the proposed measures. As has been mentioned, decisive defeats resulted in each state. The people of Arizona, California, and Oregon are to be congratulated on maintaining their standards of medical care. Apparently the majority of the voters recognized the necessity for protection against ignorance, superstition and incompetence.

THE SCHOOL PHYSICIAN

The day has gone by when the school physician should judge his success by the number of children examined or the number of defects found, says Dr. Charles H. Keene, President of the American Association of School Physicians. A large number of examinations, he points out, usually indicates hurried and careless, and, therefore, inefficient work. His success should, rather, be judged by the percentage of physical defects corrected and of immunization secured.

The school physicians, too, he adds, in the school Physicians' Bulletin, should know what is being taught, whether it is scientifically accurate, whether it is the whole truth or only a half truth. They should learn what efforts are made to have children apply to daily acts and habits

the information given them. Health information is peculiarly useless unless applied to life situations.

The school physician should be especially active in his contacts with teachers, parents, and pupils to controvert on every occasion the pernicious, blatant, and intentionally misleading advertising that pours up on teachers, parents, and children from the advertisements in newspapers, magazines, and worst of all—because it is frequently mixed with interesting and attractive entertainment—the radio. Unfortunately a large proportion of our people, old and young, believe that any statement appearing in an advertisement must be true. So far as health matters are concerned, the reverse is frequently the real case.

Medicolegal

LORENZ J BROSNAN, ESQ

Counsel, Medical Society of the State of New York

Health Officers—Court's Construction of Powers

A case decided a few years ago in a Western state serves as an interesting example of the extent to which the courts will limit the powers given to health officers.*

The State Statutes contained a provision authorizing the state board of health to designate what diseases should be considered dangerous, communicable or contagious diseases, and made it the duty of health officers to enforce such rules as the state board of health might prescribe with respect to such diseases. The state board of health acting under the statute designated gonorrhea and syphilis as dangerous, communicable diseases. By statute health officers were clothed with authority as the instruments through which the board of health acted in carrying out its powers of "general supervision of the interests of the health and life of the citizens."

A certain eighteen-year-old girl who lived a few miles from an army camp was approached by a deputy sheriff, and after a conversation with her the girl was persuaded to go with him to the office of Dr C, a city health officer. The doctor thereupon made a physical examination of the girl which was made according to her story against her will. Dr C informed the girl and her mother that she was suffering from gonorrhea, and told her she would have to go to a hospital, and if she refused her home would be placarded making public the presence of a venereal disease. She signed, at the doctor's request, admission papers for the institution, which she later claimed she signed without knowing their contents. The girl entered the hospital and at that institution a positive report was obtained from a Wassermann test. She remained in the hospital for twelve weeks under treatment for gonorrhea and syphilis. At the end of that time she was discharged as being free from the diseases in their infectious state.

The girl thereafter instituted a suit against the health officer to recover dam-

ages for assault and false imprisonment. Upon the trial the plaintiff testified to a story substantially as indicated above. Dr C did not take the stand as a witness, and so far as it appeared from the testimony, at the time he made the examination complained of he had no information with reference to the girl her habits, or her conduct, to give him any reasonable grounds of suspicion, furnished by either the deputy sheriff or any other person, to suppose that she was infected with a venereal disease. It was contended on behalf of the doctor that the girl failed to establish a case of assault and unlawful restraint and that the doctor was entitled to act as he did, and that he was under no duty to make known the nature of the information, if there was any such information, which prompted him to act as he did. The trial court adopted the view that under the circumstances the defendant's acts were justified, and ruled that the plaintiff had failed to make out a case against him, and therefore directed a verdict for the defendant.

The girl appealed to the highest court of the State, and the Appellate Court received the entire subject of the power of health officials, and finally concluded that under the circumstances as presented the case should have been sent to the jury, and therefore directed a new trial. In so ruling the Court said in part:

"There is power to protect the public health, it is vested by law in public health boards, to be exercised through reasonable rules and regulations duly promulgated. Whether such rules and regulations are lawful and reasonable, considering the true end in view and personal rights guaranteed citizens by the Constitution, constitute judicial questions beyond the power of the Legislature to foreclose.

Arbitrary power beyond the reach of redress open to an injured citizen, is not vested in boards of health or anywhere else under our system of government. While courts may well be loath to review health regulations promulgated by an executive board under legislative delegated authority, yet in a proper case the duty exists, and, no board, by executive action can close the court and succeed in having its officers remain

* R— vs C—, 185 N W 798

immune from judicial inquiry when a claimed unlawful exercise of authority has been visited upon a citizen, and redress is asked.

"Courts may be controlled by the determination of an executive board skilled as to what constitutes a dangerous communicable disease, and may not attempt to review such classification; but the method adopted or exercised to prevent the spread thereof must bear some true relation to the real danger, and be reasonable, having in mind the end to be attained, and must not transgress the security of the person beyond public necessity. * * *

"It would be an intolerable interference by way of officious meddling for health officers to assert and then assume the power of making physical examination of girls at will for venereal disease. * * * If the health officer had power at all to examine plaintiff, he had no right to exercise it without reasonable cause; such cause to precede examination and in no way to depend upon the result of examination. In any event defendant had no right to suspect and examine plaintiff so long as she had no accuser."

In the course of the opinion the court in deciding the case commented upon the history of the development of the law of public health as follows:

"Measures to prevent the spread of dangerous communicable diseases, and to provide for the isolation and segregation of these diseased, are practically as old as history. It has been said that 'the history of pestilence is the history of quarantine.'

"The law of Moses segregated the lepers, and their forced cry of 'Unclean! Unclean!' was the forerunner of the modern warning placard.

"Ancient Rome and Greece had their systems under which those infected with leprosy were separated from the well.

"In 1448 the Senate of Venice instituted a code of quarantine, and a few years earlier a regularly organized lazaretto, or pesthouse, was established.

"The Republic of Venice also established the first board of health. It consisted of three nobles, and was called the 'Council of Health'. It was ordered to investigate the best means of preserving health and of preventing the introduction of disease from abroad. Its efforts not having

been entirely successful, its powers were enlarged in 1504, so as to grant it 'the power of life and death over those who violated the regulations for health.' No appeal was allowed from the sentence of this tribunal.

"During the plague in London in 1665 the magistrates consulted to devise means for stopping, or at least impeding, the progress of the disease, and the result of their deliberations was a series of orders which appointed commissioners, searchers, surgeons, and buriers to each district, acting under certain regulations, and which directed the provisions of an old act of Parliament to be in force, for shutting up all such houses as appeared to the proper officers to contain any infected person, and every house which was visited, as it was called, was by those orders marked with a red cross of a foot long in the middle of the door, evident to be seen."

While it is not entirely clear as to whether the lower court dismissed the case at the end of the plaintiff's case or at the end of the entire case, it would seem logical to suppose that the dismissal was made at the end of the plaintiff's case. If this were not so it seems difficult to understand why the doctor and his witnesses did not testify in the case.

The ruling of the Appellate Court was based entirely upon the story told by the plaintiff. It may well be that the doctor could have given testimony if called upon to do so which would have definitely established that he had reasonable grounds to suspect that the plaintiff was a woman who in the interest of public health required an examination. Certainly subsequent events in the case proved that the doctor was right, for his examination definitely established that the woman was a menace to the health of her community. Not only the public but the plaintiff as well benefited by the treatment which she so badly needed and which without the doctor's intervention she probably never would have had.

HENRY STREET'S MIRACLE

"Present day mortality would be forty per cent higher if the system of public nursing had not been started, and the institution of home sick bed nursing by Miss Lillian D. Wald and the Henry Street Visiting Nurse Service marked the birth of public health nursing," Dr. Louis I. Dublin, vice-president of the Metropolitan Life Insurance Company, stated on November 5, 1934, at a luncheon at the Down Town Association.

"As public nursing spread, mortality dropped. Infant mortality was 20 per cent in 1893 and now is 5 per cent and less; tuberculosis claimed 300 in every 100,000 and now the figure has dropped to

sixty. There is now no real necessity of death through pneumonia or diphtheria nor is there much excuse for deaths at childbirth, which once mounted to alarming figures, if proper nursing, particularly in the home, is provided.

"Henry Street Visiting Nurses have wrought a miracle in this city. Premature deaths have ceased among the four million to which the Service ministers and its influence has spread to Europe, where whatever home nursing systems there are now, have been modeled after Henry Street."
